Complications Related to the Use of Mesh and Their Repair

Anne P. Cameron MD, FRCSC, FPMRS

The use of mesh in urology and urogynecologic procedures is one of the most controversial topics in the field of female pelvic medicine and reconstruction. Currently there are several class action lawsuits against manufacturers, and lawyers are directly targeting women who have had these procedures via advertising. Because of the risk of litigation, some mesh kit manufacturers have removed their products from the market. There have also been three iterations of the US Food and Drug Administration (FDA) Public Health Notifications surrounding the use of vaginal mesh. The unbalanced depiction of mesh and its use in the media has further frightened patients and has led some surgeons to stop performing these procedures. In spite of these challenges, well-trained urologists should not be dissuaded from using these effective products in the care of their patients.

A recent consensus statement from the Society of Urodynamics, Female Pelvic Medicine and Urogenital Reconstruction in conjunction with the American Urogynecologic Society (Nager et al., 2014) states that **“The polypropylene mesh midurethral sling is the recognized worldwide standard of care for the surgical treatment of stress urinary incontinence. The procedure is safe, effective, and has improved the quality of life for millions of women.”** This statement was issued to clarify expert opinion in light of the ongoing controversy regarding mesh use. Multiple incision mesh slings are the most extensively studied procedure for stress urinary incontinence (SUI) with more than 200 clinical trials studies describing the safety and effectiveness of this procedure (Ford et al., 2015; SCENIHR, 2015). Success rates surpass 90% and are maintained at up to 20-year follow-up with low complication rates. They remain the most commonly performed procedure for SUI in women and are recommended as a primary surgical treatment for SUI by the 2017 American Urological Association Guidelines (Kobashi et al., 2017) and the 2016 European

Association of Urology Guidelines (Burkhard et al., 2017).

Contrary to the widespread fears of mesh complications, adverse events with mesh mid-urethral sling (MUS) are uncommon. In a landmark population-based study of all incontinence procedures performed in Scotland from 1997 to 2016, mesh slings had fewer immediate complications and lower risk of future prolapse surgery than Burch colposuspension (Morling et al., 2017). Of course, no surgery is without risks, and surgeons must understand how to appropriately counsel patients before undergoing surgery and to diagnose and treat complications should they occur. In this chapter, we address the complications of polypropylene type I mesh used for the treatment of stress incontinence in women and men, as well as mesh-augmented repairs for prolapse of the anterior and posterior compartment in women as well as vault prolapse repair with abdominal sacrocolpopexy (ASC) mesh.

The terminology surrounding mesh-related complications has varied over time. The International Urogynecological Association (IUGA) and the International Continence Society (ICS) jointly have proposed a system of definitions of mesh complications that will be used in this chapter (Haylen et al., 2011). “Erosion” is a generic term that implies that tissue has been “worn away by friction or pressure” (*Stedman's*, 2005); hence it should not be used. **Exposure** is a “condition of displaying, revealing, exhibiting or making accessible” (*Stedman's*, 2005), which correctly defines mesh that is visible through separated or non-healing vaginal epithelium (Fig. 126.1A). **Extrusion** is the “passage gradually out of a body structure or tissue” (*Stedman's*, 2005), such as a loop of mesh sling protruding in the vagina or bladder not via the surgical incision site (Fig. 126.1B), and **perforation** is an “abnormal opening into a hollow organ or viscus” (Fig. 126.2) (*Stedman's*, 2005). **Contraction** is when the mesh exhibits “shrinkage or reduction in size,” and **prominence** occurs when there are “parts that protrude beyond the surface.” such as with wrinkling, bunching, or folding of the mesh without evidence of epithelial defect.

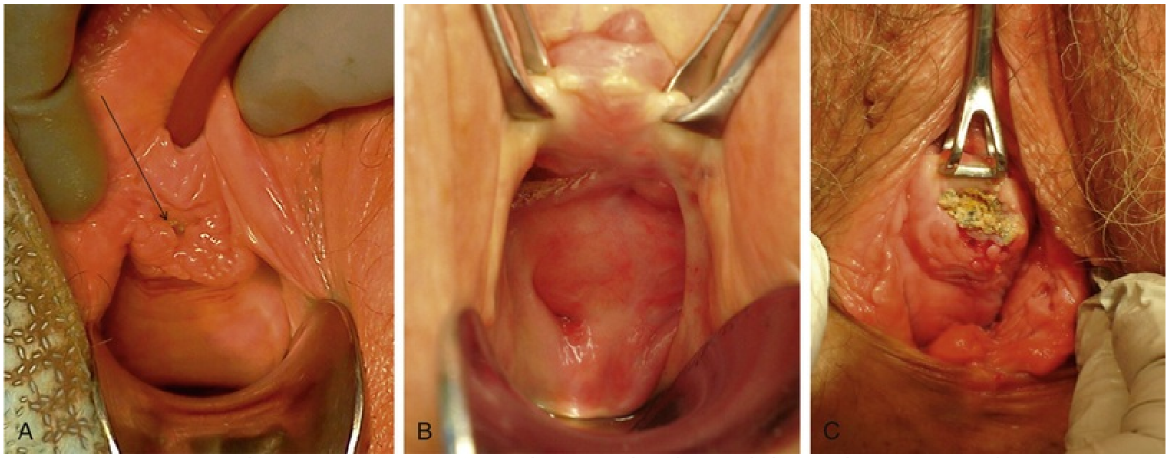

FIG. 126.1 Three examples of mesh complications. (A) Mesh exposure in the vagina from a mid-urethral sling. The incision for placement of the sling has separated and the mesh is visible. A vertical incision to access this mesh would allow for excision. (B) Mesh sling extrusion, where the mesh has gradually passed out of the vaginal epithelium away from the original incision. A horizontal incision along the area of the mesh would allow excision. (C) A pelvic organ prolapse mesh exposure/extrusion that is significantly calcified. The mesh became exposed at the original incision but has continued to become more extruded over time. Note a small central defect in the mesh where it has been trimmed in the office previously. This will require a maximal vaginal mesh excision to resolve.

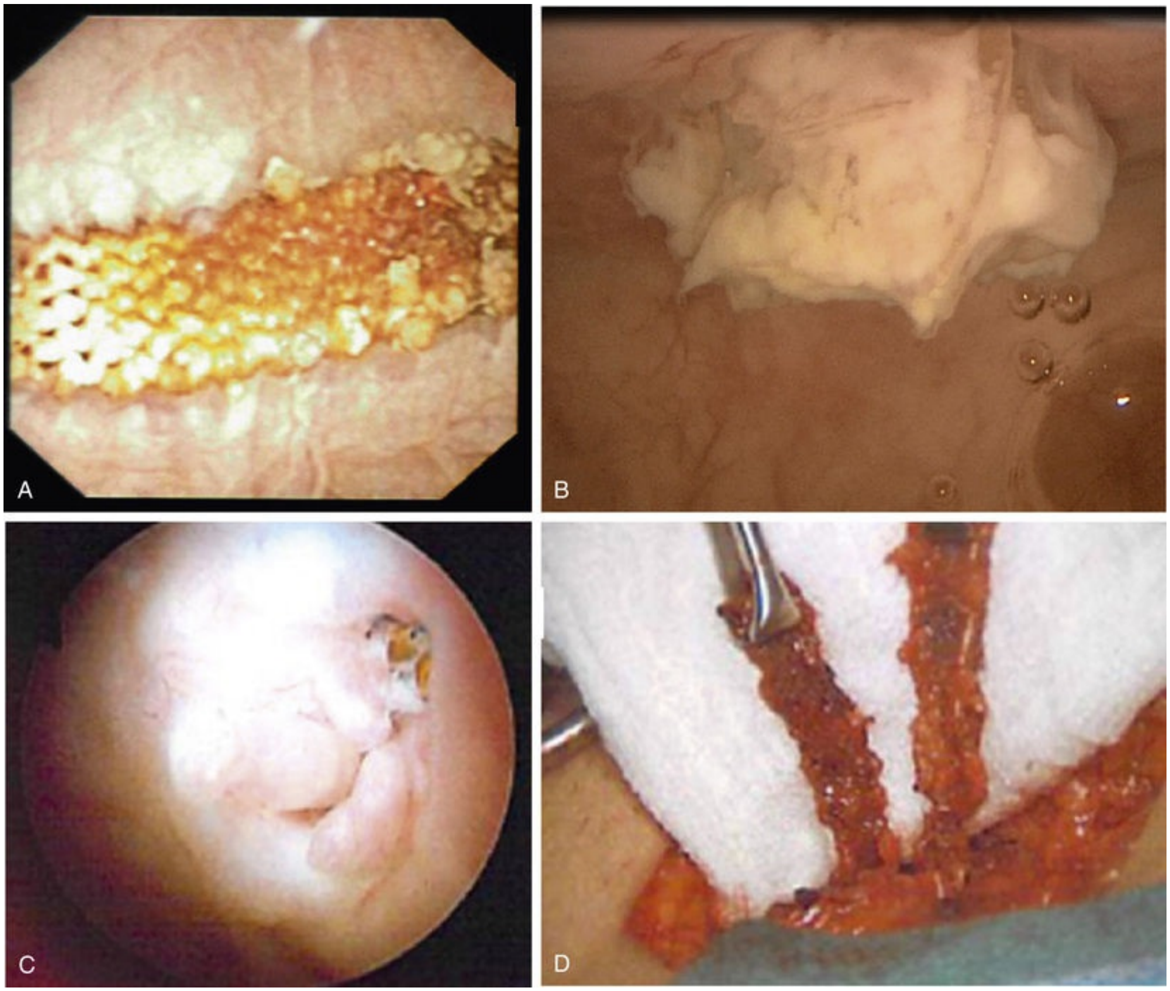

FIG. 126.2 These are all examples of bladder perforations of mesh slings. (A) A calcified mesh sling perforating the lateral bladder wall. This was discovered on computed tomography for other purposes. (B) Mesh sling at the dome seen on cystoscopy for hematuria and urgency. (C) Small mesh perforation of a mesh sling in the lateral wall of the bladder. The patient had severe pelvic pain with voiding and wanted the entire abdominal mesh removed. The arms have been located and are being dissected down to the bladder in (D).

Mesh and Its Properties

Polypropylene mesh has been widely used in surgical procedures for more than 50 years. Its success at preventing hernia recurrence has led to its use in other body compartments. Unlike the abdominal wall, the vagina has unique properties that may complicate mesh implantation, such as its significant physiologic stretch; proximity to the bladder, urethra, and rectum; and abundant microbiota.

Numerous adverse outcomes have been described with vaginal mesh implantation, including mesh infection, chronic pain, dyspareunia, vaginal exposure of the mesh, mesh shrinkage, perforation of mesh into surrounding structures, and lower urinary tract symptoms. However, there are also clear advantages to mesh over native tissue or cadaveric tissue/xenografts, including avoidance of potentially morbid harvests, lack of human or animal products that put the patient at risk for disease transmission, moderate cost, versatility, and durability (Chughtai et al., 2017).

Several mesh products have been used as mesh slings over the years with varying success and complications. According to the system proposed by Amid (1997), meshes are classified as types I to IV based on pore size. Type I mesh is macroporous with pore size greater than 75 µm. Examples of type I mesh are polypropylene and Marlex. Marlex is a woven monofilament polypropylene. It is one of the stiffest mesh materials with a propensity to wrinkle and a high extrusion rate (Morgan et al., 1995). In contrast, polypropylene is a monofilament knitted graft that is softer and more compliant than woven configurations and has larger interstices resulting from the loose knit (1500 vs. 600 µm), increasing elasticity (Gomelsky and Dmochowski, 2007). In addition, its melting point of 160°C allows it to be autoclaved. It is currently the only recommended implantable vaginal mesh for slings and pelvic organ prolapse (POP) (Chapple et al., 2017).

Type II meshes are microporous and include polytetrafluoroethylene, also known as Gore-Tex. Gore-Tex is polytetrafluoroethylene (Teflon) that has been thermomechanically expanded into a microporous mesh with a pore sized 10 µm. It becomes encapsulated in the body, which deters tissue integration, preventing adhesions. Despite success with small patch slings, more than 30% of full-length slings have required excision (Weinberger and Ostergard, 1996). Type III grafts, such as Mycromesh, have large macropores or perforations in a microporous base material (Gomelsky and Dmochowski, 2007). Other examples of type III mesh include Mersilene, which is a knitted polyethylene (polyester) that has interlinks in each fiber junction, creating elasticity in both directions. With vaginal use, complications from Mersilene, such as extrusion requiring excision and voiding symptoms, approached 20% (Young et al., 2001). Type IV grafts have submicronic pore size and include silicone grafts and silicone-coated mesh. Vaginal extrusion and sinus formation have been reported in up to 40% of cases with the use of type IV grafts (Comiter and Colegrove, 2004).

Pore size is critical to wound healing and mesh integration by the body. Smaller pore size in woven grafts allows bacteria (1 µm) to enter but restricts entry of host macrophages and lymphocytes (50 µm), impeding immune response. When pores are large, such as with polypropylene type I mesh (approximately 1500 µm), fibrocollagenous tissue ingrowth can occur, which allows the mesh to integrate into the local tissue, providing strength and support (Gomelsky and Dmochowski, 2007). Modifications have been attempted to improve tissue acceptance, such as injection of bovine collagen (ProteGen) or novel welding techniques (Urotype/Obtape), but these have produced unacceptably high rates of exposure and fistula formation (Domingo et al., 2005; Kobashi et al., 1999).

With long-term use of mesh in the vagina there has been the opportunity to follow women over many years for complications. Mesh has been hypothesized to increase cancer risk because of chronic foreign body response. This theory has been disproved with population-based studies **that showed no increase in pelvic or any other cancer diagnoses in women followed for 6 years after implant** (Chughtai et al., 2017). **Similarly mesh implantation has not been associated with the development of autoimmune diseases over long-term follow-up** (Chughtai et al., 2017). There is, however, moderate vaginal tissue fibrosis in more than half of patients, and almost all have giant cell reaction that occurs after vaginal mesh placement. Interestingly, those patients with extrusion or pain have less inflammation noted on histopathology than patients with voiding dysfunction, but overall mild inflammation predominates (Hill et al., 2015).

The USFDA approved surgical mesh for repair of POP and SUI in 2002, and these techniques were rapidly adopted. The FDA released its first Public Health Notification 6 years later, after more than 1000 mesh-related complications had been reported (FDA, 2011). This 2008 statement advised care providers that mesh has the potential for complications. In a more forceful warning in 2011, the FDA stated “serious adverse events associated with mesh use are not rare” and that “transvaginal mesh placement in pelvic organ prolapse repair does not conclusively improve clinical outcomes over traditional non-mesh repair in all patients with POP and it may expose patients to greater risk” (FDA, 2011). This warning did address ASC and concluded that “mesh placed abdominally for POP repair appears to result in lower rates of mesh complications compared with transvaginal POP surgery with mesh.” Public hearings after this warning led to an order in 2016 to reclassify POP mesh medical devices from class II, which generally includes moderate-risk devices, to class III, which identifies high-risk devices, and a second order that requires manufacturers to submit a premarket approval (PMA) application to support the safety and effectiveness of surgical mesh for the transvaginal repair of POP. The 2011 notification did not address slings for SUI, and an update was issued in 2013 to address mesh slings specifically. In contrast to its caution regarding POP mesh, **the FDA stated that “the safety and effectiveness of multi-incision slings is well-established in clinical trials that followed patients for up to one-year.”** Mesh slings for SUI remain class II devices.

These warnings have had an impact on clinical practice, particularly for POP. In a Medicare population the use of mesh in prolapse repair was only 2% in 2005 and increased to 35% in 2008. With the 2008 warning mesh use plateaued and then started to decrease in 2011 (Wang et al., 2015).

Following FDA guidelines and informing all patients that mesh will be used for their procedure is mandatory as well as providing them with written information on their product. Given the medicolegal controversy surrounding mesh, before any mesh excision it is advisable to have a standard consent form for mesh removal as well as an institutional policy for the handling of mesh being returned to patients if they desire it.

It is important to keep in mind that mesh removal is not without its own complications and the more mesh removed the greater the risks. It has been shown that more mesh removal leads to an increase in recurrent prolapse (Marcus-Braun and Theobald, 2010) and incontinence as well as excess bleeding (Pickett et al., 2015). Mesh becomes embedded in tissue and does require significant dissection to remove.

Key Point: How Much to Remove

- Surgeons should aim to remove enough mesh to correct the problem and prevent future mesh complications. Removal of all the mesh is rarely required, and removing asymptomatic mesh is never indicated.

Mesh Slings for Stress Urinary Incontinence

Unfortunately, pelvic floor dysfunction is very common: stress incontinence affects approximately one in three women and POP one in nine (Slieker-ten Hove et al., 2009). Both are strongly related to obesity, smoking, childbearing, and advancing age, and their prevalence appears to be increasing. Over the last 20 years, the lifetime risk of a woman requiring surgery for POP or SUI has risen from 11% to approximately 20% (Gyhagen et al., 2013; Smith and Koelbl, 2010).

Stress incontinence can be treated conservatively with pelvic floor physical therapy, vaginal inserts, or a pessary, but if these are not effective, a surgical approach is the next step. There are four well-established surgical treatments: urethral bulking agents, Burch colposuspension, autologous fascial pubovaginal slings (AFPVS), and multi-incision synthetic mesh mid-urethral slings (MUS) (Kobashi et al., 2017). In regard to single-incision, or “mini-slings,” “physicians may offer single-incision slings to index patients undergoing mid-urethral sling surgery with the patient informed as to the immaturity of evidence regarding their efficacy and safety” (Kobashi et al., 2017). Synthetic MUS are the most commonly performed procedure for SUI in women because they are equally as effective as the Burch and AFPVS with less surgical morbidity.

Risk Factors for Mesh Sling Complications

Avoiding mesh complications is by far the best strategy for the surgeon performing mesh MUS. There are clear contraindications to mesh implantation in the vagina, including women who are having a simultaneous urethrovaginal fistula, mesh urethral perforation, or urethral diverticulum repaired given the extensive urethral dissection in these procedures (Kobashi et al., 2017).

Other less well-defined risk factors for mesh exposure or extrusion include prior (not concurrent) urethral fistula repair, prior diverticula surgery, pelvic radiation or the presence of significant scarring, and poor tissue quality. Other potential patient risk factors include extremes of age, smoking, obesity, and low estrogenization of the vagina. These should be considered in the decision to use a mesh or non-mesh approach.

Risk factors for urinary retention after a mesh sling procedure include having had a prior SUI surgery and having concomitant vaginal apical suspension (Unger et al., 2016). Women with increased medical comorbidities (Charlson comorbidity index ≥1) are also at greater risk of failing their initial voiding trial (Ripperda et al., 2016).

Mesh Complications Among the Three Slings

Intraoperative bladder injuries occur in 4.8% of retropubic tension free vaginal tape (TVT) sling procedures. Transobturator (TOT) sling and mini-sling approaches have much lower rates of bladder injury (0–0.6% for obturator slings and mini-slings) (Fusco et al., 2017). Vaginal mucosal injury occurs in 1.6% to 7.1% of slings. Blood loss for all sling procedures is typically less than 50 mL; however, major vessel injury can occur with the retropubic approach (<1/1000) and may be life threatening (Ford et al., 2015; Kenton et al., 2015; Martinez Franco and Amat Tardiu, 2015; Mostafa et al., 2014). In addition, symptomatic pelvic hematomas occur more often in retropubic slings (1.7% vs. 0.3% in TOT slings) (Fusco et al., 2017).

Several randomized controlled trials (RCTs) showed similar mesh exposure rates with the three configurations of slings (0.7%–4.4% at 1 year) (Ford et al., 2015). This is in contrast to the mesh used in vaginal prolapse repair, in which the rate is much higher at 10% to 12% (Abed et al., 2011; Glazener et al., 2017), likely because of the greater surface area of mesh placed.

Groin pain is much more common after obturator (12%–26%) and mini-sling (~1.5%) approaches and likely relates to passage of the tape near the adductor muscles, but groin pain has been reported after retropubic sling. Voiding dysfunction resulting from obstruction is more common after retropubic slings (0.3%–7%) than the TOT slings (0–4%) or mini-slings (1.4%–1.7%). De novo symptoms of overactive bladder occur in 0 to 7% of cases and may be related to obstruction, which should be ruled out (Ford et al., 2015; Fusco et al., 2017; Kenton et al., 2015; Mostafa et al., 2014). Rarer complications include bowel perforation, nerve injury, and obturator/vaginal abscess (all <1%). Overall in long-term population studies 5.9% of women will require a mesh revision over 5 years (Keltie et al., 2017).

A thorough history including review of prior operative reports (from mesh implantation and attempts at excision) as well as a good speculum pelvic examination are required in all cases of suspected mesh complication. Cystoscopy can be performed if there is any suspicion of mesh perforation into the bladder. These perforations can be accompanied by hematuria, recurrent infections, LUTS, or sharp bladder pain, particularly when voiding. The time elapsed from surgery does not exclude the possibility of a complication: patients who had slings placed decades ago can still have new mesh exposures (Khanuengkitkong et al., 2013).

Bladder Outlet Obstruction and New Urgency and Urgency Incontinence

Bladder outlet obstruction (BOO) can easily be diagnosed in the woman after sling placement who has frank retention or elevated postvoid residuals. Also women with new obstructive urinary symptoms such as straining, double voiding, slow stream, or the need to assume unusual positions such as crouching to void are obvious and often do not require urodynamics to diagnose. It is important to determine the temporal association of the retention. **Women with prior difficulty emptying may have underlying pathology such as detrusor underactivity or diabetes, but in women who voided well before sling placement the cause is most likely the sling. In contrast, new or worsening urgency urinary incontinence (UUI) or urgency may be secondary to BOO from the sling, or it may simply be the result of bladder overactivity**. Women without overt retention often take longer to diagnose (on average 6 months) (Crescenze et al., 2016), which is concerning because irreversible bladder remodeling can occur with long-term bladder obstruction (Leng and Chancellor, 2004). Urodynamics are required in this instance, particularly in the woman who has failed a short course of antimuscarinics for urgency after sling placement. New-onset recurrent urinary tract infections after a sling may also be the presentation of BOO, and urodynamics are indicated to determine if this is the case.

Urethral dilation is ineffective in the setting of BOO from an obstructing sling and puts the patient at risk for urethral extrusion of the mesh with the dilation traumatizing the tissue over the inflexible mesh (Velemir et al., 2008). If the patient is improving, short-term voiding dysfunction can be managed expectantly for up to 6 weeks. However, if the patient is in retention, intervention should be much sooner because it is unlikely to resolve (Committee Opinion 694, 2017). If done within the first week, the sling can be loosened by opening the vaginal incision, placing an instrument around the mesh, and tugging. If the sling is embedded in the tissue and does not loosen, then the sling can simply be divided. Any frayed edges should be trimmed away from the incision. Before division of the sling, the amount of urethral mobility can be assessed by pulling on the catheter; after division, this should be appreciably improved.

Vaginal Mesh Exposure and Extrusion

Mesh exposure and extrusion likely occur as a result of a delayed infection of the incision or mesh, a vaginal hematoma that leads to separation of the incision, excess tension on the graft, or inadvertent injury to the vagina with mesh placed too superficially within the vaginal wall (Chermansky and Winters, 2012). **Exposures and extrusion occur with persistent bleeding, vaginal discharge, dyspareunia, partner pain, recurrent UTIs, or pelvic pain.** All of these concerns warrant a pelvic exam (Committee Opinion 694, 2017). Small exposures can sometimes spontaneously re-epithelialize, especially in the early postsurgical period, and this can be facilitated with short-term topical estrogen (Committee Opinion 694, 2017).

Different approaches have been reported, such as laparoscopic mesh removal (Rouprêt et al., 2010); however, **most surgeons aim to only remove the offending part of the sling, which can be accomplished vaginally in most cases.** Surgical excision of the mesh is typically performed under general anesthetic. If the mesh location is visibly exposed or obvious on palpation, an incision can be made either vertically midline or along the mesh horizontally (particularly if there is a large exposure) (see Fig. 126.1B). If the mesh is not appreciated on exam, an inverted U-shaped incision offers maximal exposure to explore for the mesh and allows the flap to be extended proximally as needed. Before incision, hydrodissection with 1% lidocaine with epinephrine facilitates flap creation by maximizing epithelial thickness over the mesh. The surgeon should not accidentally divide the mesh while making the vaginal incision because this makes mesh localization difficult. If the mesh is not easily palpated, a metal instrument can be used to sound over the dissected space because mesh can be “felt” as a scratching over the area. Alternatively, intraoperative translabial ultrasound can localize mesh very accurately (Staack et al., 2014). Mesh is not always located in its expected location mid-urethrally. It can be found as distal as the urethral meatus and can migrate proximally past the bladder neck. Once the mesh is found, careful blunt and sharp dissection is performed to expose the full width of the sling lateral to the urethra. This careful exposure allows easy passage of an instrument behind the sling, avoiding injury to the urethra. The instrument is then spread and the sling cut. Each arm can be dissected laterally to the lateral sulcus of the vagina and with tension divided as far as the surgeon can safely pass the scissors. If the mesh exposure is small, the surgeon can consider removing at least a centimeter of mesh around the defect (Fig. 126.3). Care must be taken not to blindly dissect laterally, especially with obturator slings, because there are many vessels in this location and a postoperative hematoma of the vulva can result (Fig. 126.4). Care must also be taken not to injure the urethra when passing the instrument behind the sling. If the urethra is injured, it should be repaired in layers and a catheter left in place. The vaginal mucosa is closed with a running 3-0 absorbable suture. Patients can have their catheters removed before discharge, unless bladder or urethral injury is noted.

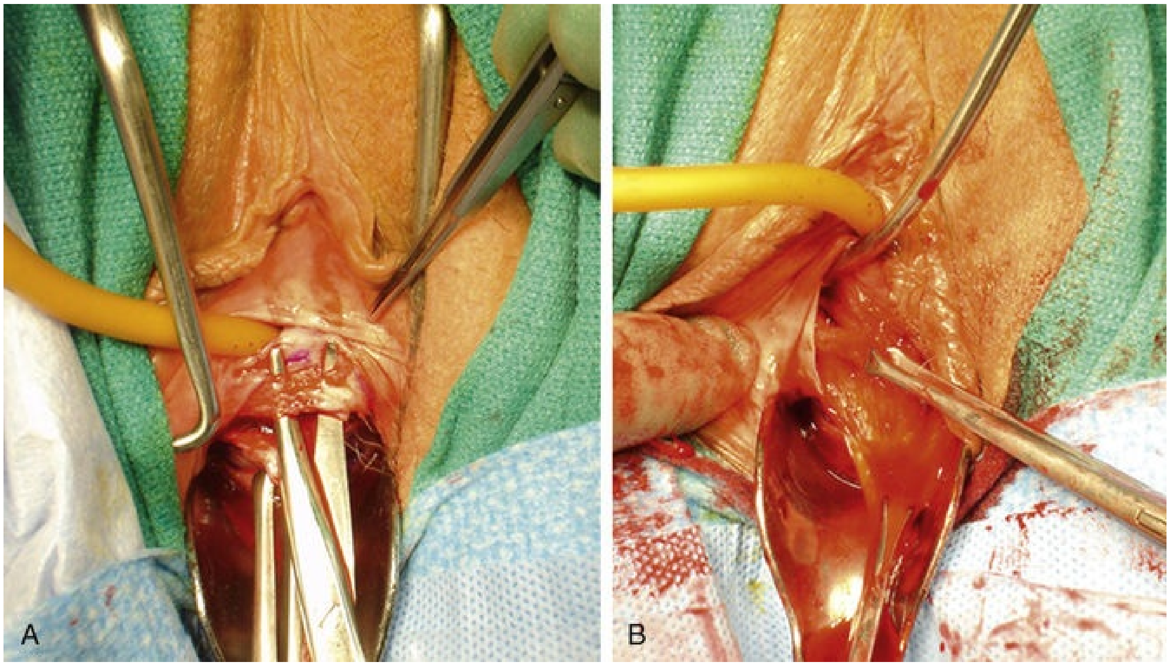

FIG. 126.3 This is the “divide-and-conquer” technique for mesh sling removal. (A) Once the mesh is found and the edges defined, an instrument (with sharp tips pointing out) is passed behind the sling lateral to the urethra and divided. (B) The arms can then be used for traction to easily dissect them as far as needed for resection.

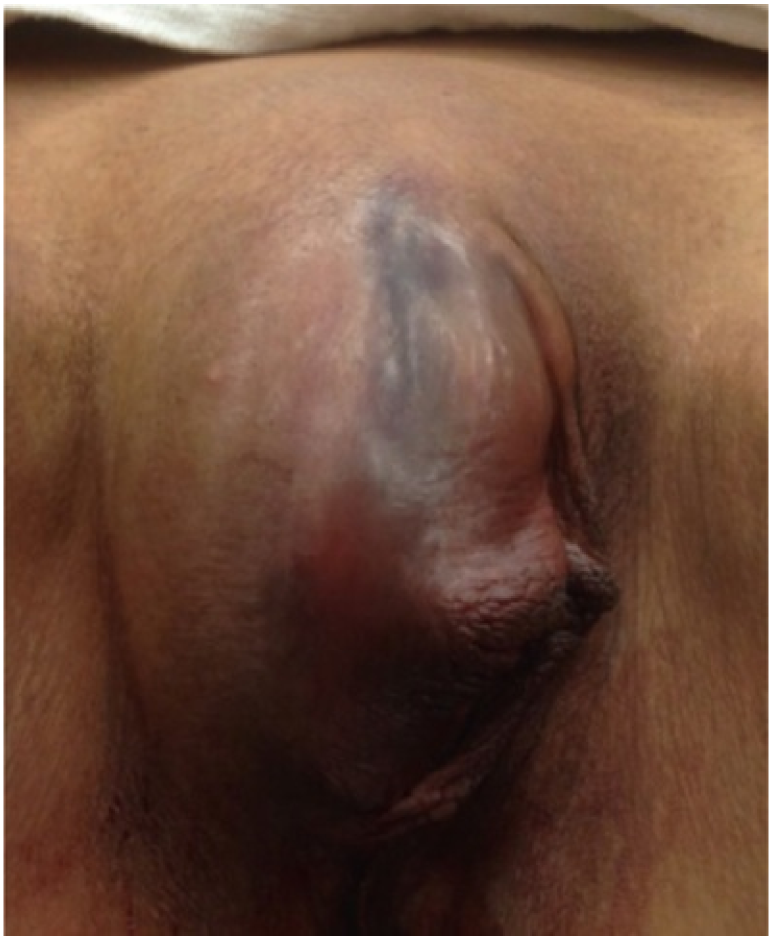

FIG. 126.4 This is a rapidly expanding vulvar hematoma after vaginal removal of an obturator sling. Patient required open evacuation via the vaginal incision, and the bleeding resolved with suture ligation of bleeding and vaginal packing.

Vaginal, Pelvic, and Thigh Pain

Pain after an MUS in the absence of other complications such as exposure or retention is a diagnostic challenge. It requires a detailed history of prior pain conditions (fibromyalgia, endometriosis, dyspareunia) and a focused physical exam of the pelvic floor attempting to isolate the source of the pain.

Preoperative risk factors for the development of pain after a sling include younger age, pain conditions such as fibromyalgia, or preexisting pelvic pain (Geller et al., 2017). Pain has been proposed to be caused by mesh shrinkage, excess tension on surrounding structures, obturator neuralgia, or muscle hypertonia from mesh being placed through pelvic floor muscles (Rigaud et al., 2010).

Pain that is severe and occurs acutely after a sling placement in the absence of other complications should be evaluated immediately. Many chronic mesh pain patients describe their pain as occurring immediately postprocedure. Although this is untested, it would seem legitimate to consider rapidly removing a mesh sling in the case of severe postoperative pain because mesh removal procedures are straightforward before tissue ingrowth (Rigaud et al., 2010). Before proceeding with mesh removal, the urologist should obtain cross-sectional imaging to rule out hematomas, because they are a common cause of discomfort and will likely resolve over time.

Diffuse pelvic floor hypertonicity or unilateral levator hypertonicity will benefit from oral analgesia and pelvic floor physical therapy or trigger point injections as a first step. Dyspareunia can also be the result of vaginal atrophy and lack of lubrication rather than the sling, and a trial of vaginal estrogen should be considered in postmenopausal women. Point tenderness over the sling or failed conservative treatment warrants consideration of mesh excision.

Removal of the entire vaginal portion of the sling reduced pain from 5.3 to 1.5 (on a 10-point scale), and 81% of women considered themselves pain free. If the indication for mesh removal is vaginal pain, it is important that as much vaginal mesh as possible is removed because persistent pain can be very difficult to treat if mesh is left behind. Patients with persistent pain after mesh removal tend to report diffuse pelvic pain (Hou et al., 2014) and should be treated conservatively with anti-inflammatory agents, topical estrogen, or physical therapy.

Groin Pain

Transient groin pain occurs frequently after TOT sling but typically lasts only a few weeks. Pain that is persistent and recalcitrant to conservative therapy such as oral analgesia, local injection, or steroid/nerve blocks can be treated with TOT excision of mesh. This can be accomplished via TOT foramen dissection combined with a vaginal dissection (Reynolds et al., 2012). Lateral groin incisions are made over the inferior pubic ramus at the level of the obturator foramen. This approach requires division of the adductor brevis medially, which is the most superficial muscle over the foramen. The obturator externus is directly below, and the mesh can be found within. After vaginal exposure of the mesh and dissection vaginally to the obturator foramen, traction on the mesh can facilitate localization of the mesh in the thigh. In the case of prior vaginal mesh removal, obturator exploration alone can be performed but is very challenging without the vaginal end for traction (Reynolds et al., 2012). Once the mesh is found, it is dissected medially toward the vaginal end of the mesh, and it is removed in a single segment. In a small case series, obturator foramen dissection resulted in complete pain resolution in 5 of 8 patients (Reynolds et al., 2012). This is not a straightforward dissection and may be unfamiliar to the urologist; orthopedic surgery assistance can be of value.

Complications of Vaginal Mesh Removal

Vaginal mesh sling removal can cause bleeding or injury to the vagina, bladder, or urethra, and mesh can become re-exposed over time. Severe bleeding is rare, but hematomas can be difficult to manage because they take significant time to resolve. Storage voiding symptoms can be refractory to sling excision. In women who develop UUI secondary to BOO from a sling 76% have persistent UUI after sling division (Crescenze et al., 2016). In women undergoing sling revision for BOO without concomitant urgency, up to 45% may develop de novo UUI after surgery.

After sling division or excision, the risk of recurrent SUI is not negligible. Reported rates of recurrent SUI vary from 20% to 74% (Clemens et al., 2000; Marcus-Braun and Theobald, 2010; Misrai et al., 2009; Moore and Goldman, 2013) and up to one-third will require another surgical procedure to treat it (Ramart et al., 2017). Bulking agents (Gaddi et al., 2014), repeat mesh sling (Parden et al., 2013), and autologous pubovaginal sling (Milose et al., 2016) have demonstrated success in women with recurrent or persistent incontinence after MUS or recurrent incontinence after sling removal. It is an individualized decision, but many patients with a sling complication requiring excision will be hesitant to have mesh implanted again.

After a simple sling division 95% of patients will have resolution of retention requiring catheterization, and 75% will have resolution of their obstructive symptoms (Crescenze et al., 2016). Persistent obstructive symptoms may be the result of continued obstruction from the sling, detrusor underactivity, or voiding dysfunction. Urodynamic studies are the most effective method of differentiating between these causes and determining the best course of action. If a repeat sling excision is indicated, a larger section of sling should be removed and a more aggressive urethrolysis performed to avoid continued obstruction.

Key Points: Mesh Removal Principles

- Mesh slings should be circumscribed and divided lateral to the urethra.
- The amount of mesh removed depends on the indication: retention requires only simple division; for exposure/extrusion, divide and remove mesh to at least a centimeter from defect; pain requires maximal vaginal removal and rarely, pubic or obturator arms.

Bladder Injury and Perforation/Extrusion

Bladder injury is far more common with retropubic than TOT trocars (4.8% vs. 0.6%) (Fusco et al., 2017) and is typically diagnosed on cystoscopy with a 70-degree lens during the sling placement. The trocar is seen at the dome/lateral wall of the bladder. **Complete filling of the bladder is required to evaluate for injuries because an underfilled bladder may obscure a small perforation.** Risk factors for trocar perforation include low body mass index (BMI; < 30) because there is less adipose tissue in the retropubic space displacing the bladder away from the pubic bone (Osborn et al., 2014) and prior incontinence surgery. Surgeons should ensure the bladder is completely drained before trocar passage and that the trocars remain in contact with the pubic bone during passage. The trocar must be rolled back and forth and the bladder mucosa examined to rule out intramuscular trocar placement, which is indicated by tethering or a trocar visible through thin mucosa. If not replaced, this can predispose a patient to future mesh extrusion into the bladder lumen. If a trocar perforation is detected in the bladder, the trocar is simply removed and replaced with great care (Fig. 126.5). Even if recognized and replaced correctly, bladder perforation does increase the risk of mesh extrusion into the bladder (Osborn et al., 2014). Missed bladder perforation can occur with pelvic or vaginal hematoma in the perioperative period; therefore if this complication does occur, suspicion for an unrecognized injury should be high (Osborn et al., 2014).

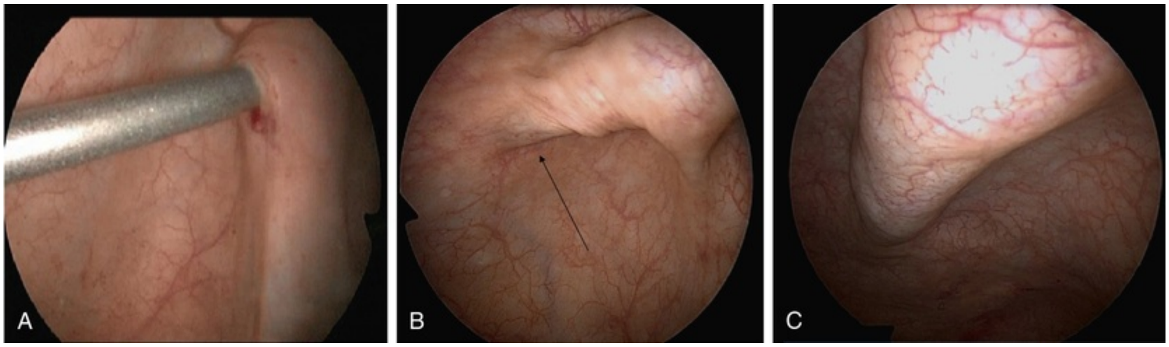

FIG. 126.5 These are different cystoscopic appearances of retropubic mesh sling trocars. (A) Clear perforation of the bladder with the metal trocar and requires removal and replacement. (B) Trocar in the detrusor muscle. It has not perforated the mucosa, but the metal is visible through the mucosa *(arrow)* and the bladder wall is wrinkled. (C) Same patient after removal and replacement of the trocar. The bladder is maximally filled and the indent in the bladder rolls smoothly; this is the correct placement of a trocar.

Bladder perforation/extrusion can present with irritative voiding symptoms (41%): vesicovaginal fistula, recurrent UTI, vaginal pain/dyspareunia, and hematuria (Osborn et al., 2014; Padmanabhan et al., 2012). These symptoms often occur immediately after sling placement and warrant a cystoscopy (Deng et al., 2007). If mesh is exposed to urine for prolonged periods, it will often form calculi that are seen on imaging (see Fig. 126.2A).

Bladder perforations can be treated with endoscopic resection or open cystotomy. Those bladder injuries that are close to the bladder neck or are after TOT sling placement can often be approached vaginally similarly to urethral injury. Endoscopic management has been performed with holmium laser, hysteroscopic scissors, or transurethral resection of the mesh with electrocautery loop into the bladder wall. If there is significant stone burden on the mesh, it should be treated first to clear the mesh. This approach is low morbidity and will often resolve symptoms (Foley et al., 2010). Following an endoscopic approach, the mesh is still embedded in the detrusor wall and will require monitoring for subsequent extrusion. If this occurs, open excision is advisable (Padmanabhan et al., 2012).

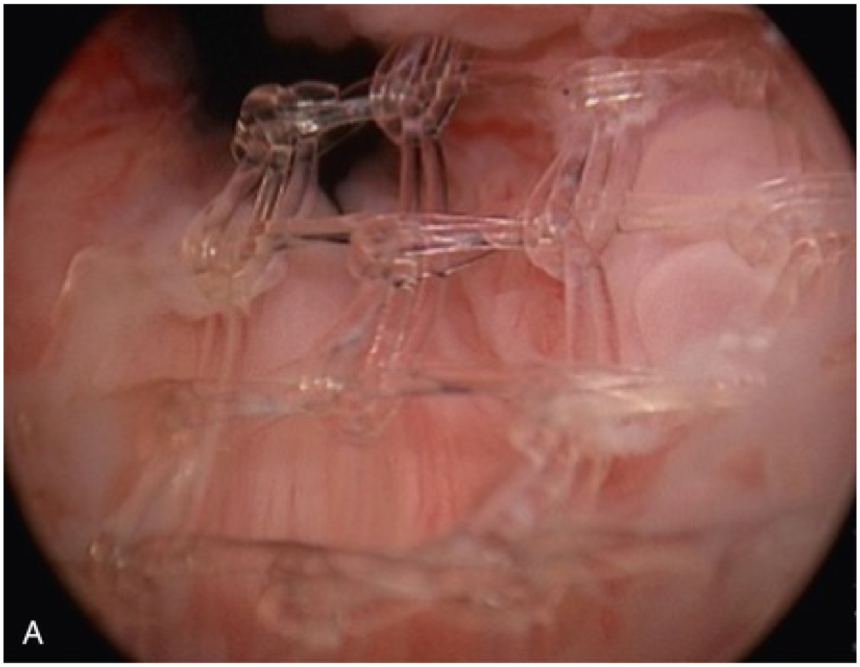
Transvesical removal of a larger section of mesh within and outside the bladder is a more definitive approach but has greater morbidity. It has been performed laparoscopically (Misrai et al., 2009) or via open abdominal incision (Foley et al., 2010; Shah et al., 2013).

With the patient under general anesthetic the prior pubic exit incisions from the retropubic sling can be marked as reference for where the arm of the sling will be expected. A cystoscopy confirms the laterality of the mesh perforation and allows placement of a ureteral access catheter if the mesh removal potentially compromises the ureteric orifice. A Pfannenstiel incision is made through skin and down to fascia and the superficial fascia exposed because the arms can often be found superficial to it. The offending arm once found can be used as traction and the fascia opened and the arm tracked down along the bladder. Only the mesh and its pseudocapsule are excised with an aim to remove no native tissue. Once the bladder is entered, the sling must be dissected past the defect and for another 2 cm to prevent the bladder closure from incorporating mesh. If the patient is not having vaginal pain, then the vaginal portion nor the contralateral arm need be removed. The resulting bladder defect can be closed in two layers with absorbable suture and the repair tested by filling the bladder via the catheter. With this approach there is almost no risk of re-extrusion of the mesh. If a patient had preexisting stress incontinence, this is an ideal opportunity to perform an autologous sling (Shah et al., 2013). The catheter can be removed 2 to 3 weeks postoperatively after a cystogram.

Mesh Perforation/Extrusion at Bladder Neck or Urethra

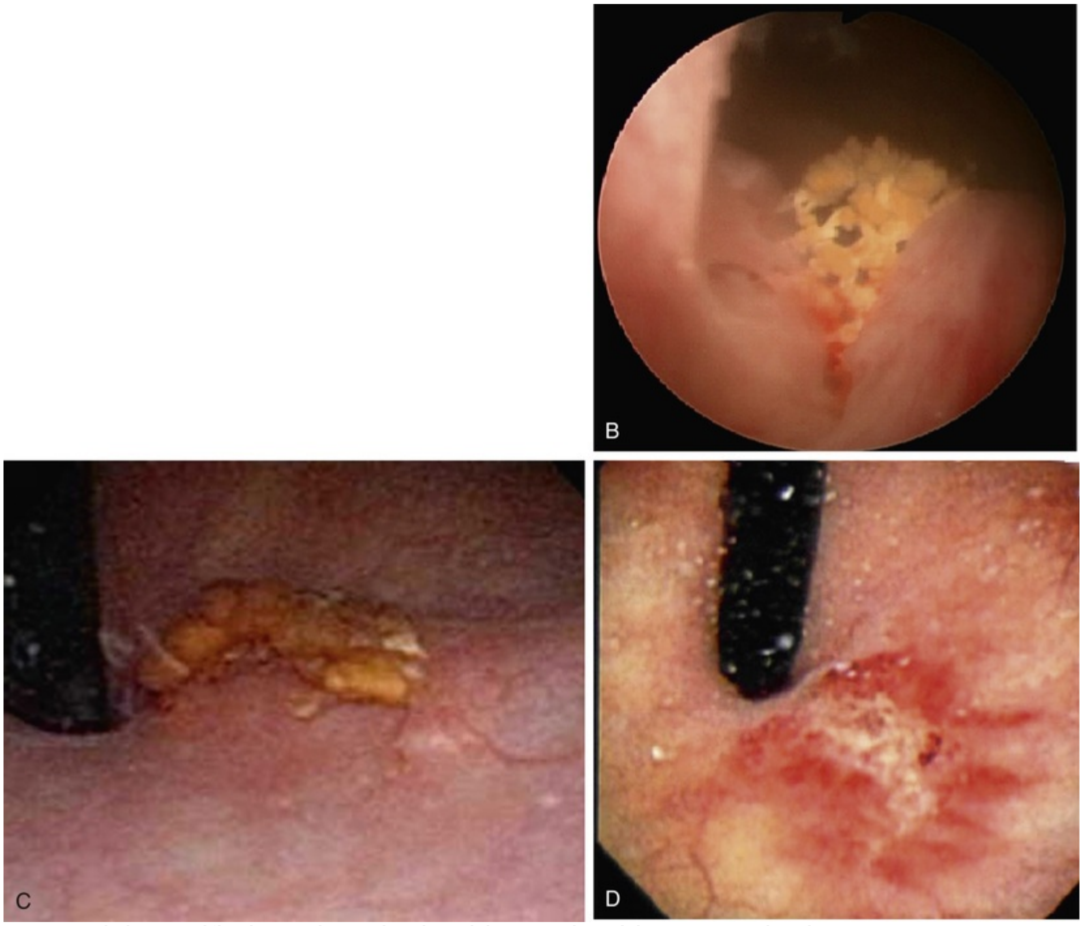
Mesh perforation or later extrusion at the bladder neck or into the urethra is a rare complication. It occurs because of an injury to the urethra or bladder neck during either the vaginal dissection or trocar passage. **If an intraoperative urethral injury is noted during dissection for placement of the sling, the surgeon must abandon mesh placement** (Kobashi et al., 2017). One should repair the urethral injury with absorbable suture and allow healing before undertaking any mesh procedure, given the extraordinary high risk of urethral extrusion of the mesh. Aggressive sling over-tensioning may also result in late urethral mesh extrusion, as can urethral dilations. As such, it is best to avoid urethral dilations and proceed to sling division if a patient is obstructed after sling placement.

Women with mesh in the urethra experience sharp pain during voiding or dysuria; retention; urgency; pelvic, urethral, and vaginal pain; hematuria; and recurrent infections. Symptoms often begin immediately after surgery (Deng et al., 2007; Velemir et al., 2008). A careful urethroscopy will reveal the mesh perforation (Fig. 126.6).



These are cystoscopic appearances of mesh perforation of the urethra. (A) Mesh perforating along the diameter of the urethra. This patient had minimal symptoms and was successfully treated with endoscopic scissors. (Courtesy J. Quentin Clemens.)

Velemir et al., 2008).



(B) Calcified mesh at the bladder neck. This woman had worsening of her incontinence after the sling placement along with severe voiding pain and recurrent urinary tract infections. She required urethrolysis and complete vaginal removal of the sling. (C and D) Mini sling. The perforated trigone/bladder neck was covered in stones on image C even after stone removal was symptomatic; hence it was removed vaginally (see Fig. 126.7). Note the proximity to the ureteric orifice in the right corner of image D.

FIG. 126.6

Endoscopic removal has been reported and can be accomplished with endoscopic scissors or a holmium laser. This is facilitated by traction placed on the mesh with an instrument passed along the cystoscope. Alternatively, a small nasal speculum can be used to directly access the mesh in the urethra for excision. This approach does leave mesh in the urethral wall that can extrude into the lumen in the future but is minimally invasive (Baracat et al., 2005; Velemir et al., 2008).

Urethrolysis with removal of entire vaginal mesh is a more definitive approach because no mesh is left near the urethra. After cystoscopy confirming the location of the injury, an inverted U-shaped flap is created after hydrodissection with 1% lidocaine. The mesh is found lateral to the urethra on the opposite side of the mesh injury if possible. The arm on the uninjured side is dissected up to the lateral sulcus and divided. The mesh is then carefully peeled off the urethra, knowing that it traverses the urethra proper, taking care to not excise any tissue and just remove the sling. Once the urethra is entered, care must be taken to create the smallest defect possible. Overdissection of the urethra can injure the continence mechanism or increase the risk for stricture. In the case of mesh in the bladder neck, if the initial cystoscopy reveals mesh near the ureteric orifice, a temporary ureteral access catheter can be placed for safety.

If the mesh perforates the urethra along its diameter, the urethra may have to be entered via a midline urethrotomy to facilitate complete extraction of the mesh. Alternatively, the mesh can be divided in the lumen with a cystoscope and hysteroscopic scissors and the arms dissected lateral to the urethra and pulled through each side, leaving only two small defects where the mesh was perforating (see Fig. 126.6).

Careful closure is necessary to prevent urethrovaginal fistula formation. The urethra is closed primarily with absorbable suture and a periurethral fascial layer developed and closed over the injury where possible (Deng et al., 2007). If there was a fistula associated with the mesh in the urethra or tissue quality is poor, the surgeon may consider a Martius flap to cover the defect, particularly if the patient will desire a future sling. The vaginal flap is then advanced and closed using a running absorbable suture avoiding overlapping suture lines. If the patient has a concomitant urethral stricture, a formal urethroplasty with buccal mucosa can be performed to correct the defect (Fig. 126.7).

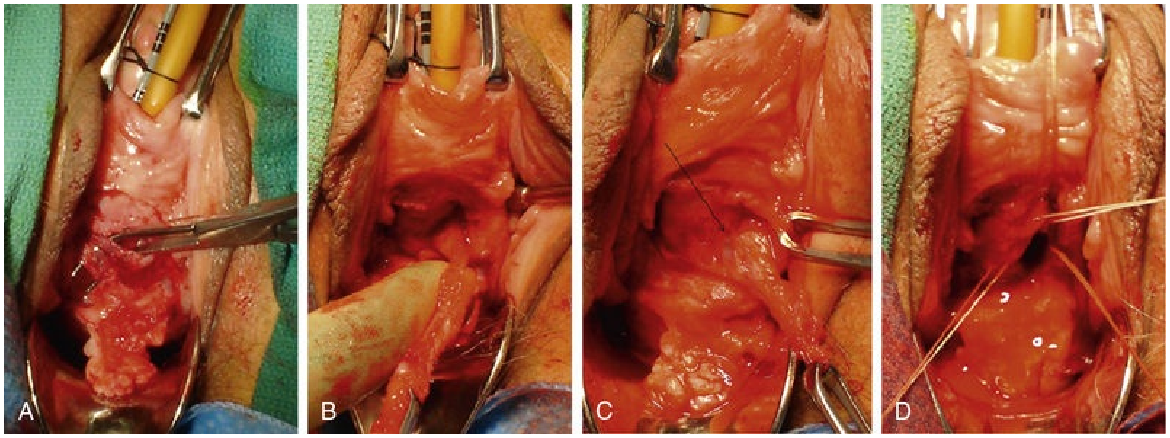


FIG. 126.7 These are the steps of mesh excision from the urethra/bladder neck from Fig. 126.6C and 126.6D. (A) The mesh has been localized and is being circumcised and divided. Note the ureteric access catheter placed to allow localization of the ureter. (B) The uninvolved right side of the sling has been excised, and the left arm is being dissected toward its perforation. (C) The mucosa of the bladder neck *(arrow)* is visible as the perforation is just about to be entered. (D) The resulting defect is closed after the mesh is removed.

Forty-two percent of patients develop SUI after intraurethral mesh excision (Starkman et al., 2006); however, the simultaneous placement of an autologous fascial pubovaginal sling significantly lowers that risk. New or persistent urgency and urgency incontinence is also very common (Starkman et al., 2006).

Key Point: Bladder and Urethral Perforations

- Bladder and urethral perforations are difficult complications to treat and can be managed endoscopically or open; the open approach is more thorough but associated with potentially greater morbidity.

Transvaginal (Anterior and Posterior Wall) Mesh Complications

Mesh kits for the treatment of anterior and posterior compartment prolapse have been used since 2004. Although anterior mesh was decreasing in use since the FDA warnings (Wang et al., 2015); both anterior and posterior mesh have been withdrawn from the market; many patients have already had these implants and may be seen at a later date with complications requiring treatment.

Nearly all surgical mesh devices used for these procedures are composed of nonabsorbable synthetic macroporous polypropylene (type I). Many different manufacturer kits are available with different shapes, anchoring devices, and configurations and are placed via midline vaginal incision on the anterior or posterior vaginal wall. Because each product has variations in its attachments, obtaining the original operative report of mesh placement is extremely valuable (Committee Opinion 694, 2017).

Mesh kits were developed to increase the ease and durability of POP repair. Native tissue repairs have been reported to have failure rates as high as 30% to 97% in the anterior compartment (Maher et al., 2016). However, this perceived inferiority has been brought into question with a recent large randomized controlled trial comparing primary transvaginal anterior or posterior repair using native tissue, biologic graft, or mesh placed transvaginally. This largest trial of its kind ($n = 1358$) found that after 2 years there were no differences in POP symptom scores or POP-related quality of life. Non–mesh-related adverse events such as UTI, urinary retention, and dyspareunia were not different between groups (~7%); however, 12% of the mesh group suffered a mesh-related complication, and three-quarters required either total or partial surgical excision (Glazener et al., 2017).

Mesh exposure or extrusion can present with serosanguineous or seropurulent discharge, dyspareunia, pelvic pain, or irritation to the partner's penis from exposed mesh (hispareunia) (Khrucharoen et al., 2018). Extrusions have been reported to occur up to 8 years after mesh placement; therefore any patient with mesh and symptoms requires an examination (Marcus-Braun and Theobald, 2010). Small mesh exposures (<1 cm) can be asymptomatic in up to 60% of women (Cheng et al., 2017). The rate of exposure is 10.3% to 12% (Abed et al., 2011; Glazener et al., 2017), with 5.1% to 8% requiring mesh removal (Dandolu et al., 2017; Diwadkar et al., 2009; Glazener et al., 2017).

Mesh contraction (shrinkage) occurs in 11.7% (Caquant et al., 2008) and is unique to POP mesh because a much larger volume of mesh is implanted. It can cause dyspareunia, vaginal shortening, and vaginal tightening. Another unique complication of POP mesh is folding and wrinkling of the mesh, creating a prominence that has no epithelial separation but can cause patient or partner pain with intercourse. This is seen on examination as palpable tight bands or heaped up areas that are tender to palpation. Patients can also have vaginal constriction or obstructed defecation after transvaginal mesh (Abbott et al., 2014).

Mesh perforation into the bladder (Altman et al., 2011; Caquant et al., 2008)

(0.7%–3.5%) in the case of anterior compartment POP repair and into the rectum (Caquant et al., 2008) (0.15%) from posterior repair can occur with pain, fistula formation, or, in the case of bladder perforation, recurrent hematuria, UTIs, or voiding-related pain. This is fortunately rare with a fistula rate of 0.2% reported (Caquant et al., 2008; Diwadkar et al., 2009). Other rare complications include pelvic hematoma (1.9%) and pelvic abscess (0.29%). Most patients (70%) experience multiple symptoms, and it is uncommon to have only one distinct complaint (Abbott et al., 2014).

Surgical risk factors for mesh exposure are a higher volume of mesh implanted (such as dual-compartment or POP mesh combined with a mesh sling) (Chughtai et al., 2017; Dandolu et al., 2017; Rac et al., 2017) and inadequate depth of vaginal dissection (Altman et al., 2011). Patient risk factors include smoking, diabetes, hypertension, extremes of age, being sexually active, concurrent hysterectomy, prior hysterectomy, and previous prolapse repair (Caquant et al., 2008; Cheng et al., 2017; Dandolu et al., 2017).

Treatment of Prolapse Mesh Complications

Mesh exposures in the vagina can be treated conservatively, particularly if the woman has few symptoms, there are no signs of infection, and the exposure is less than 0.5 to 1 cm. Treatments include observation only or topical estrogen cream (Committee Opinion 694, 2017), which may promote epithelialization. Notably there is no risk to observing an asymptomatic monofilament macroporous mesh exposure. Other minimally invasive approaches include in-office cautery with silver nitrate or in-office trimming of the mesh. In series in which a conservative approach is discussed, 25% to 36% of patients with mesh exposure do not require surgical excision (Cheng et al., 2017; Glazener et al., 2017). No patient factors such as age, BMI, smoking status, or menopausal status predicted success of conservative approaches to mesh exposure except size of the exposure (Cheng et al., 2017). Office-based excision with local anesthetic can be challenging because of limited visualization and patient discomfort. Close follow-up should be planned in these cases because up to 60% will require surgical treatment, and of those women who have in-office trimming, 73% eventually require excision in the operating room (Abbott et al., 2014).

Dyspareunia and pelvic pain in the absence of exposure or mesh abnormalities such as folding or prominence on exam are not well described in the literature. Given their normal physical exam systemic analgesics can be attempted in the short term and physical therapy particularly if there is pelvic floor hypertonicity contributing to the pain. Nerve block or trigger point injections can also be attempted in women who want to avoid surgical excision of the mesh (Warembourg et al., 2017). **Pelvic pain related to non-exposed POP mesh is a complex problem and may not resolve after mesh removal** (Committee Opinion 694, 2017); therefore conservative treatments are worth an attempt. In one series that assessed pain resolution after vaginal mesh removal in women without exposure, 67% were pain free after maximal transvaginal mesh excision (Hou et al., 2014).

Surgical Mesh Removal

If a woman is symptomatic or has a large exposure that will not heal conservatively, excision is the next step. Patients must be counseled about the risks of mesh removal, including the need for repeat mesh excision. Also patients need to be aware that, no matter how thorough the mesh removal, small areas of mesh will likely remain. The best approach is to aim to remove enough mesh to resolve symptoms and prevent future mesh complications while avoiding causing complications for the sake of removing more mesh.

A good exam under anesthesia should be performed at the beginning of any mesh excision as well as a cystoscopy if there is any suspicion of bladder perforation and rectal examination or proctoscopy in the case of posterior mesh. The limits of the mesh can typically be palpated on the exam, but if they are difficult to locate, a vaginal ultrasound can be performed intraoperatively.

For anterior and posterior wall mesh typically a midline full-thickness vaginal incision is made over the expected location of the mesh to be removed. Before incision hydrodissection over the entire area of excision with 1% lidocaine with epinephrine will assist with creation of a vaginal flap and control bleeding. A self-retaining retractor along with a weighted vaginal speculum can assist with exposure. The vaginal epithelium is opened with a scalpel and flaps of vaginal epithelium developed sharply superficial to the mesh with an aim to make the flap as thick as possible to prevent tears or buttonholes. The superior and inferior edges of the mesh must be identified and dissected free of the vaginal epithelium. A right angle or tonsil clamp is carefully passed behind the mesh and the mesh is then divided. This is a critical part of the procedure because bladder or rectal injuries are most likely to occur during this portion of the dissection, which is relatively blind. Once the mesh is divided in the midline, each portion can be used for traction to carefully dissect the rectum or bladder off of the mesh. The dissection is done sharply with scissors (tips pointing away from the bladder or rectum) and with gentle blunt dissection. Dissection is carried out to the lateral arms of the mesh and, once visualized, strong tension is applied while these arms are cut, maximizing the amount of mesh removed. At the location of arm excision, bleeding is often encountered, and the surgeon must be ready to suture ligate bleeding vessels. Excess pursuit of lateral arms can result in hematoma formation. During dissection in the ischiorectal fossa a finger placed in the rectum can assist in preventing inadvertent entry. Before closure a native tissue anterior colporrhaphy with absorbable suture or posterior repair can be undertaken to prevent prolapse recurrence in this compartment. The vaginal incision is trimmed of any devitalized tissue and closed using a running locked absorbable suture (Ridgeway et al., 2008). Cases with smaller areas of exposure without pain, infection, or fistulas can be tailored to remove less mesh, provided a healthy, thick flap of vaginal epithelium free of mesh for at least 1 cm can be obtained.

Complications of transvaginal mesh removal include UTI, vaginal yeast infection, and temporary urinary retention. Later common complications include cystocele recurrence (19%) (Marcus-Braun and Theobald, 2010), new-onset incontinence, or the need for repeat surgery to remove more mesh (20%) (Marcus-Braun and Theobald, 2010). Rare complications include bladder injury (1%), hematoma formation (2%), and vesicovaginal fistula (3%) (Warembourg et al., 2017).

No specific patient factors such as diabetes, age, obesity, or smoking predict complication after mesh removal (Rac et al., 2017), but **patients with pre-existing chronic pain conditions have a greater risk of persistent vaginal pain after excision** (Crosby et al., 2014). Those with persistent pain tend to have diffuse pelvic pain rather than pain at a specific site (Hou et al., 2014). When more mesh is removed, the risk of prolapse recurrence is greater (Marcus-Braun and Theobald, 2010), but partial mesh removal incurs a greater risk of subsequent mesh excisions. Patients who have mesh excised from multiple compartments simultaneously have a threefold estimated blood loss (50 mL vs. 150 mL) with a ninefold increased risk of transfusion (1% vs. 9%) (Pickett et al., 2015). Hematomas can be managed expectantly or with antibiotics if there is suspicion for infection. However, if the hematoma is rapidly expanding or the patient shows signs of acute blood loss, she should return to the operating room for evacuation and hemostasis.

Long term, patients may have persistent symptoms, including discharge (22%), bleeding (15%), and dyspareunia or pain even after complete resolution of mesh exposure. Patients must be counseled that mesh removal, even if a "success," may not resolve these bothersome symptoms. Persistent sexual dysfunction is especially common, and 45% of women report sexual abstinence after mesh removal because of mesh-related problems. This must be particularly emphasized in women who have other chronic pain diagnoses because their pain is more likely to be unresponsive to mesh excision (Crosby et al., 2014).

Key Point: Prolapse Mesh Complications

- Transvaginal prolapse mesh has a higher rate of mesh exposure/extrusion than slings, given the larger volume of mesh. Small exposures can be treated conservatively. Large exposures and pain are treated with vaginal mesh excision; typically the entire vaginal mesh is excised, leaving only the arms in place. Vaginal pain/dyspareunia is the most difficult to treat, given the multifactorial cause of pain.

Apical Mesh Complications

ASC using polypropylene mesh is an extremely durable prolapse repair with a reoperation rate for prolapse of only 2.2% (Diwadkar et al., 2009; Gupta et al., 2018). Non–mesh-related complications that are commonly reported include inadvertent cystotomy (2.6%) and wound infection (2.4%). Other less common complications include ureteral injury, small bowel obstruction (0.7%), enterotomy (0.3%), and port site herniation (0.3%) (Gupta et al., 2017: Hudson et al., 2014).

Mesh-related complications can be either exposures (in the setting of concomitant hysterectomy or vaginal repair) or extrusion into the vagina, typically at the apex where the mesh is anchored. Less common mesh complications include pain (2.3%) (Hudson et al., 2014); mesh perforation into the bladder or bowel after surgery, which are likely secondary to unrecognized cystotomy or enterotomy; pelvic abscess; and discitis (Gupta et al., 2017). The rate of mesh exposure after ASC was initially believed to be far less than with vaginal placement of mesh, but with increasing follow-up in large, well-designed studies, the rate of exposure increases over time with the probability at 7 years being 10.5% (Nygaard et al., 2013).

Several risk factors for extrusion of mesh after ASC have been consistently reported. Patients having a uterine or cervical-sparing ASC are at very low risk of extrusion because the cervix acts as an anatomic barrier. Conversely having a concomitant total hysterectomy at the time of ASC significantly increases the risk of exposure compared with women having ASC post-hysterectomy (23% vs. 5%) (Tan-Kim et al., 2011). Greater stage of prolapse (3–4) and undergoing multiple concomitant procedures also increase the risk of mesh extrusion. Other risk factors such as smoking, diabetes, age, BMI, bowel resection, posterior repair, and hormonal status have variably been shown to affect extrusion risk (Cundiff et al., 2008; Diwadkar et al., 2009; Visco et al., 2001).

Mesh extrusion/exposure occurs in a similar fashion as in other compartments of the vagina, with purulent or bloody vaginal discharge, dyspareunia, granulation tissues in the vagina, palpable mesh by patient or sexual partner, and pelvic pain. Abdominal or vaginal cuff abscess can occur within a few weeks to several months after ASC with abdominal or pelvic pain, foul vaginal discharge, and fever (Akyol et al., 2014). Because a large portion of the mesh after ASC is not accessible via vaginal exam or transvaginal ultrasound, cross-sectional imaging is often required. MRI provides the best visualization because the mesh is visible; with CT the mesh is not seen.

Treatment of Mesh Exposure

The simplest mesh complication to treat is suture extrusion into the vagina. Most ASC are secured to the abdominal side of the vagina with several nonabsorbable sutures such as expanded polytetrafluoroethylene (ePTFE, Gore-Tex), polypropylene, or polyester. These soft sutures can present as an extrusion early or late and have similar, albeit often less severe, symptoms as mesh extrusion. They are diagnosed with a good speculum exam (Fig. 126.8).

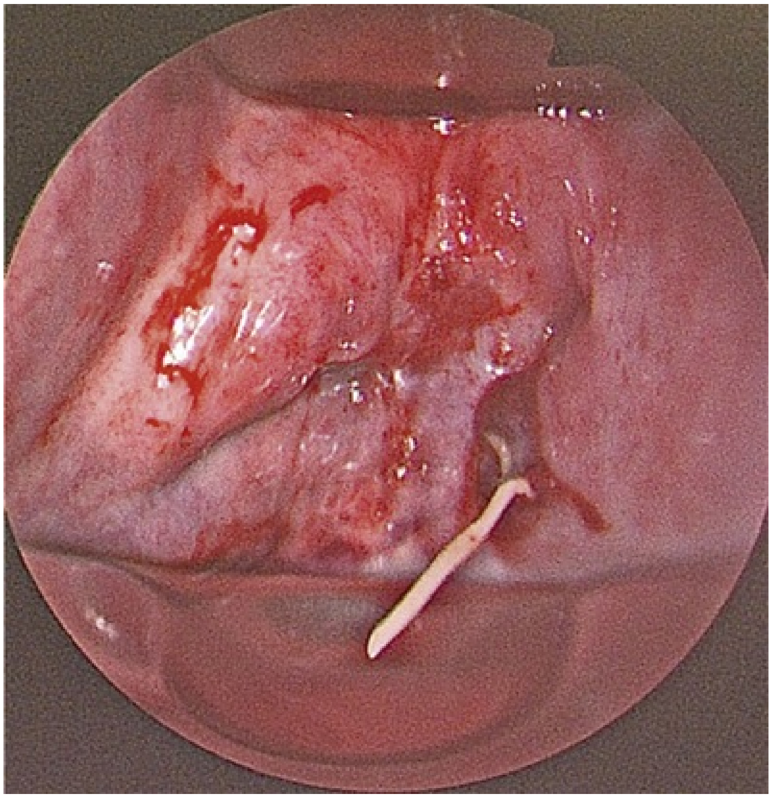

FIG. 126.8 An extruded permanent suture from an abdominal sacrocolpopexy. Symptoms included bleeding and discharge. It was treated by a simple division of the stitch below the knot.

These are straightforward to treat because the suture can be grasped and the suture cut deep to the knot to release the entire suture. Typically, the vaginal defect is so small that no suturing is required. The patient should be treated with vaginal estrogen to promote healing after the suture is removed. The ability to put traction on the suture makes this feasible and effective as an office procedure (Cundiff et al., 2008; Nygaard et al., 2013).

For small mesh exposures, topical estrogen cream applied with the vaginal applicator to achieve good tissue penetration at the superior portion of the vagina, where the exposure is located, has very little prospective or comparative data. A 6- to 8-week trial of this therapy is reasonable particularly with a small mesh exposure without any significant inflammation or in the patient who is minimally bothered (Committee Opinion 694, 2017; Cundiff et al., 2008). The available evidence notes a 14% resolution (Deffieux et al., 2006).

Mesh excision vaginally is a less invasive approach than mesh removal abdominally. In contrast to extruded sutures, these excisions can be far more challenging. A vaginal epithelium incision is required. The mesh is very difficult to manipulate because of its high attachment in the abdomen, and most of these women have excellent anatomic support of the vault, which makes access more difficult. As with anterior and posterior meshes, simply trimming the exposed mesh is bound to fail because the mesh burden is so high adjacent to the incision. The vaginal approach does carry a high risk of mesh extrusion recurrence and in some series required up to three attempts to resolve (South et al., 2007). A technique involving a partial colpocleisis has been reported to be successful in 50% of cases (Quiroz et al., 2008). The authors describe placing a suture for traction through the exposed mesh with sharp dissection of the vaginal epithelium for at least a centimeter around the exposure until healthy vaginal tissue well ingrown with mesh is encountered. A maximal amount of mesh is excised, and the remaining mesh is inverted and closed with absorbable suture. The vaginal epithelium is then closed with a delayed absorbable suture.

Abdominal mesh removal is sometimes indicated after failed vaginal approach or for patients with intractable mesh-related pain, abscess/infected upper portion of the mesh, or discitis. **In the case of infection, the entire mesh should always be removed because residual infected mesh after a failed partial excision causes significant morbidity including chronic infection, sinus tracts, abscess, and fistula formation.** These will require a repeat excision typically via laparotomy, and this is usually a very difficult and morbid procedure (Cundiff et al., 2008). The abdominal approach also allows for the concomitant correction of other abdominal complications such as ureteral obstruction or ureterovaginal fistula and would be the preferred approach in these instances.

During abdominal removal the mesh must be detached all the way from the sacral promontory to the vaginal cuff, including removal of any nonabsorbable attachment suture. The mesh is often in a retroperitoneal location because many surgeons “re-peritonealize” the ASC mesh during initial placement. The mesh is often very adherent to adjacent tissue. The mesh is typically found in the expected location; however, case series have reported mesh found near the coccyx or in other locations very distal to the sacral promontory (Oliver et al., 2017), and the surgeon must proceed with care. Partial vaginectomy or trachelectomy to remove the entire mesh is frequently necessary (74%) (Oliver et al., 2017) because the mesh is deeply embedded in the vagina. Blood loss can be substantial, ranging from 200 to 1000 mL when performed in an open fashion (Oliver et al., 2017). Other complications include bowel injury in up to 29% (South et al., 2007) of cases and sepsis. Given the morbidity of the abdominal approach, most authors recommend complete mesh excision because a repeat abdominal excision would be needed in the event of recurrent exposure, infection, or pain and subsequent procedure are even more difficult. Case series in which the mesh is completely removed abdominally as an initial procedure have reported up to 100% symptom resolution (South et al., 2007).

Laparoscopic approaches have also been described (South et al., 2007), but given the difficulty of this procedure being performed, open laparoscopic approach would be even more challenging. Individual surgeons must judge their own ability with advanced laparoscopic techniques when deciding on an approach for this uncommon surgical procedure. South et al. (2007) reported no difference in complications between the two approaches to remove ASC mesh, but these patients were selected for the most appropriate approach on a case-by-case basis.

Key Point: Abdominal Sacrocolpopexy Mesh Removal

- ASC sutures are easily removed vaginally; however, mesh is very difficult to effectively remove transvaginally, often requiring multiple attempts. Open abdominal mesh removal is a potentially morbid procedure with high risk of bowel injury, vaginal tissue loss, and significant blood loss.

Male Mesh Slings

Men are also affected by SUI, occurring most commonly after radiation or radical prostatectomy for prostate cancer. Men have a very low reported incontinence mesh complication rate in the literature, and the use of mesh in men is much less controversial than in females. The lower rate of complications likely occurs because the incision is in the perineum, which is a sterile procedure with no expected bacterial contamination in contrast with the vaginal route for women. Also the mesh is placed deep to the epidermis and underlying subcutaneous adipose tissue with several layers of closure over the mesh. Furthermore, the bulbar urethra is very thick ventrally where the mesh is placed in contrast to female urethras, resulting in a very low urethral extrusion rate.

Perineal bone-anchored slings (**AMS Invance**, Minnetonka, MN) involve securing a 4- × 7-cm silicone-coated polypropylene mesh to the inferior rami with four to six titanium bone screws attached to a polypropylene suture via a perineal incision. Although this procedure is no longer performed, the urologist may encounter the need to remove or divide one of these devices for complications or to allow placement of an artificial sphincter. Removal is relatively straightforward because the coated mesh is not as ingrown with patient tissue as woven type I polypropylene, and, if infected, will be even less ingrown. The prior perineal incision can be opened sharply and dissection carried down to the mesh. Once the mesh is found, the superior and inferior edges should be dissected and an instrument passed behind the sling, taking care to avoid the urethra. The mesh can be divided and each arm dissected toward the pubic rami. The bony anchors (2–3 on each rami) can be challenging to remove if the bone is intact and could be removed with a rongeur; however, because these are surgical steel, they rarely needed to be taken. The mesh can be extracted from the bony screw entirely with careful dissection. Sling division without actual removal is sometimes needed when placing an artificial sphincter and can be performed simultaneously without difficulty (Fisher et al., 2007).

The Virtue Quadratic male sling (Coloplast, Humbebaek, Denmark) has TOT components as well as prepubital arms that relocate the urethra and provide perineal urethral compression to achieve continence (Comiter et al., 2014). It is made of large-pore knitted monofilament polypropylene with four arms and a central portion placed over the bulbospongiosus muscle.

Three studies have reported on medium-term outcomes and complications

(Comiter et al., 2014; Ferro et al., 2017; McCall et al., 2016). **Short-term urinary retention occurs in 0 to 44% of patients but only persists for up to 3 days.** No cases required any intervention other than extending the duration of catheterization. **Short-term paresthesia has been reported in up to 12% of men, and perineal and scrotal pain is very common postprocedure, occurring in 14% to 17%. Chronic perineal pain has been described in 0 to 7% of men and has been treated with sling removal.** No urethral perforations or infections of the sling have been reported in the literature, but this is the newest of the male slings with a small overall number of procedures. Removal of the perineal portion of the sling has been reported and can be accomplished to allow for placement of an artificial sphincter in the case of sling failure.

The Advance TOT sling (Boston Scientific, formerly American Medical Systems) is a macroporous knitted monofilament polypropylene sling. A second-generation sling, the Advance XP was launched in 2010 with integrated tensioning fibers and a broad center portion to allow fixation to the corpus spongiosum. It functions by repositioning the native sphincter into its original presurgical position without compressing the urethra (Bauer et al., 2011). The sling is placed directly on the bulbar urethra with no bulbourethral muscle intervening. It is the most commonly used sling in North America. Between **14% and 21% of men experience acute urinary retention** after removal of the catheter (Bauer et al., 2010; Serra et al., 2013). **Most resolve within a few days once the edema from the procedure abates, but 0.5% to 1% of men have chronic retention lasting more than 12 weeks. Men with cystoprostatectomy and neobladder as the cause of their incontinence are at particularly high risk of retention** (100% in one study; Bauer et al., 2010). Retention can also occur as do novo overactivity with urgency incontinence. This can be diagnosed urodynamically and treated with sling transection on one or both sides of the urethra. Avoidance of transection immediately over the urethra reduces risk of urethra injury.

Perineal pain has been reported in 2.2% to 8% (Bauer et al., 2010; Serra et al., 2013) **and has been treated with oral analgesia with persistent pain occurring in 0.4% to 1% with none requiring mesh explant.**

Urethral extrusion of mesh is one of the more severe complications of any of the male slings and is accompanied by urinary retention, pain, hematuria, and urinary tract infections. It is easily diagnosed with urethroscopy, and any male with persistent retention should receive a cystoscopy as part of his workup. In case series in which it has been reported, it occurred in procedures in which cystoscopy was not performed during the procedure and was believed to result from a urethral perforation during the procedure (Bauer et al., 2010). This author has two cases: one with no cystoscopy during the procedure and the other with traumatic catheterization after sling placement in the presence of prior radiation (Fig. 126.9).

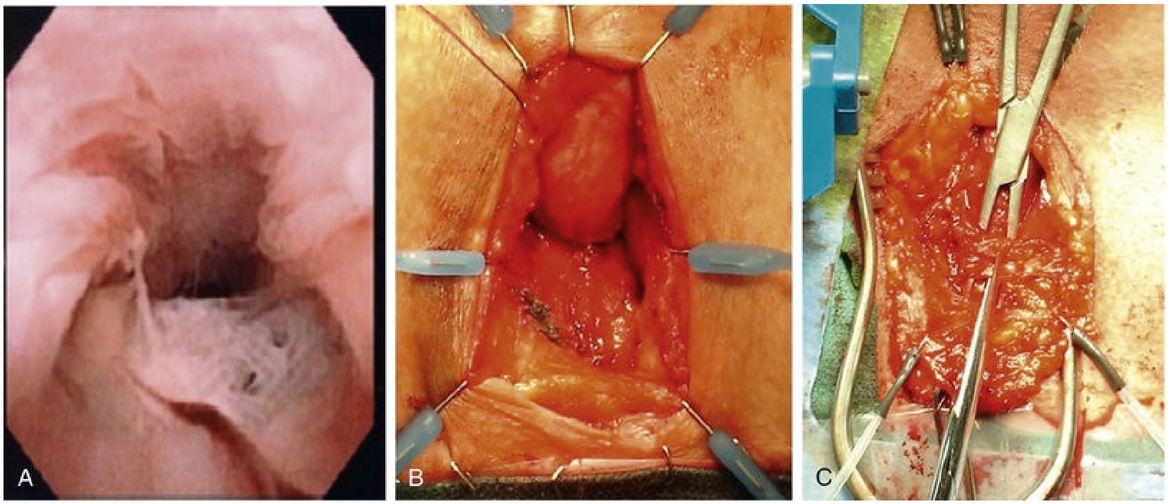

FIG. 126.9 (A) Male sling that has perforated and is obstructing the urethra. The patient experienced pyuria and retention. (B) This is the appearance of the sling before it was divided. (C) Division of the sling lateral to the urethra. The mesh was later dissected out of the bulbar urethra and the defect repaired primarily because there was little stricture.

Excision is performed by circumscribing the mesh lateral to the urethra on both sides and dissecting toward the urethra with an aim to preserve the urethra maximally. If the urethra is extensively involved or there is stricture accompanying the mesh perforation, consideration should be made for an augmented ventral buccal graft. Given the patient's prior urethral transection during radical prostatectomy, avoiding transecting the urethra seems prudent.

Key Point: Male Slings and Retention

- Male slings often have temporary retention that typically resolves over time. It is uncommon to require mesh division to resolve it, and urodynamics are helpful in determining obstruction versus bladder dysfunction as the cause.

Additional Therapies for Storage and Emptying Failure

Timothy B. Boone MD, PhD, Julie N. Stewart MD, Laura M. Martinez MD

Disorders of the storage and emptying phases of micturition result in voiding dysfunction and often lead to bothersome urinary symptoms. The location of the storage or emptying failure may occur at the bladder, the bladder outlet, or a combination of both. Storage failure originating from the bladder results from poor bladder compliance, decreased capacity, detrusor overactivity (DO), and/or altered bladder sensation. Failure of the bladder outlet to store urine is due to an incompetent closure mechanism. Emptying disorders can similarly be classified by location. At the bladder level, impaired or absent detrusor contractility leads to emptying failure. At the bladder outlet, emptying difficulties are caused by anatomic obstruction or sphincter dyssynergia/dysfunction. In previous chapters, numerous therapies for bladder storage and emptying failure have already been discussed, illustrating the complexities of voiding dysfunction management.

This chapter covers additional therapies to improve bladder storage and emptying, including contemporary augmentation cystoplasty techniques for adults, surgical and nonsurgical management of the incompetent bladder outlet, and modified cystoplasty incorporating a catheterizable channel.

Additional Therapies for Storage Failure at the Bladder Level

Failure of the filling/storage phase of micturition often results in urinary symptoms of frequency, urgency, and/or incontinence. In addition, poor bladder compliance and reduced capacity may lead to renal function deterioration. **The goals of therapy for storage failure are urine accommodation in the bladder at low pressures, improved bladder capacity, decreased incontinence related to DO, and preservation of renal function.**

Augmentation Cystoplasty

Augmentation cystoplasty is a well-established technique that typically involves adding an enteric segment to the bladder to increase its size. This can improve bladder compliance and capacity, preserve renal function, and minimize incontinence resulting from severe DO. **Augmentation cystoplasty may be performed in patients who have failed or who are not candidates for more conservative forms of intervention such as anticholinergics, intravesical instillation of medication, intravesical injection of botulinum toxin, and/or clean intermittent catheterization (CIC).** The contemporary indications for augmentation cystoplasty are narrowing with the rising efficacy of these conservative therapies, especially botulinum toxin, and their ability to improve bladder compliance and capacity (Karsenty et al., 2008). However, augmentation cystoplasty plays an important role in the management of refractory patients. In the appropriate patients, augmentation cystoplasty is an excellent treatment option that can enhance bladder function and improve patients’ quality of life.

Historical Perspective

First reported in canines by Tizzoni and Foggi (1888), augmentation ileocystoplasty was performed in humans 1 year later by Von Mikulicz (1889). After 1972, with the introduction of CIC and the wider use of enteric segments in urologic procedures, the technique of augmentation cystoplasty gained popularity (Biers et al., 2012). In 1982 Bramble's technique of clam cystoplasty (1982), further popularized by Mundy and Stephenson (1985), established the use of augmentation cystoplasty in the urologic community.

More recently, the number of augmentation cystoplasty procedures being performed has declined. Data from the United Kingdom show a 38% reduction in augmentation cystoplasty operations from 2000 to 2010. This reduction appears to coincide with a dramatic increase in the use of intravesical botulinum toxin (Biers et al., 2012). The decline also may be related to increasing concern for complications associated with augmentation cystoplasty, including malignancy, spontaneous bladder perforation, and metabolic changes (Schlomer et al., 2013). However, in a prospective study of 30 patients with refractory neurogenic bladder resulting from spinal cord injury (SCI), quality-of-life and continence rates were significantly higher in patients who had augmentation cystoplasty versus those managed with intravesical botulinum toxin; complete continence was achieved in 87.5% vs. 42.3% ($P = 0.0187$) (Anquetil et al., 2016).

Indications for Augmentation Cystoplasty

The key indications for augmentation cystoplasty are poor bladder compliance, reduced bladder capacity, and significant refractory DO.

Bladder Compliance.

It is well known that patients with poor bladder compliance and/or subsequent increases in detrusor pressures of greater than 40 cm H_2O without leakage during bladder filling are at risk for vesicoureteral reflux and upper tract deterioration (McGuire et al., 1981). Patients with poor compliance require intervention to reduce storage pressures, thereby preserving renal function. Multiple studies show that augmentation cystoplasty successfully reduces detrusor pressures and improves bladder compliance. In the literature, there is a reported 65% to 82% reduction in mean maximum detrusor pressure after augmentation cystoplasty (Gurung et al., 2012; Khastgir et al., 2003; Quek and Ginsberg, 2003). In addition, long-term data with 6 to 14 years of postoperative follow-up show this improvement in compliance to be sustained over time (Gurung et al., 2012; Khastgir et al., 2003; Quek and Ginsberg, 2003). After augmentation cystoplasty, resolution or marked improvement in vesicoureteral reflux is also reported (Khastgir et al., 2003).

Capacity.

Reduced bladder capacity, found in conjunction with poor bladder compliance and/or severe DO, is another indication for augmentation cystoplasty. **Patients with significantly reduced bladder capacities are bothered by incontinence, frequent urination, and/or the frequent need to perform CIC to avoid leakage.** These bothersome lower urinary tract symptoms (LUTS) negatively affect patients' social, psychological, and physical quality of life (Ku, 2006; Liu et al., 2010). Patients who have undergone augmentation cystoplasty have improvements in bladder capacity with an increase in mean cystometric capacity from 200 mL to more than 500 mL postoperatively (Gurung et al., 2012; Khastgir et al., 2003; Khavari et al., 2012; Quek and Ginsberg, 2003). In addition, after augmentation cystoplasty, patients have significant improvement in their quality of life and a 93% to 96% satisfaction rate (Gurung et al., 2012; Khastgir et al., 2003).

Detrusor Overactivity.

Augmentation cystoplasty is also indicated in patients with severe DO refractory to anticholinergics, intravesical botulinum toxin, and/or neuromodulation. **DO is a urodynamic finding characterized by involuntary detrusor contractions during filling cystometry.** DO can result in significant urinary urgency, frequency, and/or incontinence. A systematic review demonstrated that patients with neurogenic DO incontinence scored lower on various health-related quality-of-life instruments measuring physical, emotional, and psychological parameters when compared with their continent counterparts (Tapia et al., 2013). Overall continence rates in patients with neurogenic DO also improve after augmentation cystoplasty and range from 80% to 100% (Biers et al., 2012). Although augmentation cystoplasty is not commonly performed for idiopathic DO, data show similar continence and satisfaction rates of 78% to 90% in this population (Edlund et al., 2001). Not surprisingly, urinary incontinence from neurogenic DO also negatively affects patients' sexual function (Valtonen et al., 2006).

Augmentation Cystoplasty Techniques

Many gastrointestinal tract segments have been used for bladder augmentation. These segments include ileum, sigmoid colon, cecum, and stomach. Each is associated with its own advantages and disadvantages. A more detailed discussion of various augmentation techniques and complications may be found in Chapter 37.

Ileocystoplasty is the most common type of augmentation cystoplasty because of the reconstructive urologist's familiarity with ileum and the ileum's ability to easily reach to the pelvis. Although hyperchloremic metabolic acidosis can occur after using ileum or colon for bladder substitution, the use of ileum for augmentation seems to result in less significant metabolic disturbances. Patients with SCI followed for more than 10 years after ileocystoplasty had no evidence of metabolic abnormalities (Gurung et al., 2012). Normal electrolyte and arterial blood gas levels were also found after long-term follow-up of 25 pediatric patients with ileocystoplasty. However, 12% of these patients had mild osteopenia, a potential sequela of chronic acidosis (Hafez et al., 2003). Although patients may develop metabolic acidosis after ileocystoplasty or colocystoplasty, this acidosis is often clinically insignificant and only 16% require oral bicarbonate therapy (Biers et al., 2012).

Colon has also been successfully used for augmentation cystoplasty. The sigmoid can be redundant in chronically constipated neurogenic patients, is easy to position on the bladder, and has a large lumen and abundant mesenteric blood supply. One advantage of using cecum, or the ileocecocystoplasty technique, is the ability to use the ileocecal valve along with terminal ileum to create a continent catheterizable channel (Sarosdy, 1992; Sutton et al., 1998). **Disadvantages of using large bowel instead of small bowel for augmentation include more significant metabolic disturbances** (Vaida et al., 2003)**, increased mucus production, and a theoretic heightened risk for malignancy. Before augmentation cystoplasty, colonoscopy is recommended in all patients in whom colon will be used. Using the terminal ileum for ileocecocystoplasty also puts patients at risk for vitamin B_{12} deficiency. Thus levels must be monitored over the long term.**

When small or large bowel is unavailable or metabolic acidosis is present, **stomach is an option** for use in bladder augmentation. **The advantages of gastrocystoplasty are decreased mucus production and less bacterial colonization.** The popularity of gastrocystoplasty has waned with increasing awareness of associated complications. **Hematuria-dysuria syndrome occurs in up to 70% of patients with gastrocystoplasty** and is characterized by suprapubic pain, dysuria, bladder spasms, and hematuria. However, only 4% of patients with this syndrome will require chronic treatment with H_2 blockers or proton pump inhibitors (Leonard et al., 2000). **Other complications include peptic ulcers in the bladder, augment perforation, hyperchloremic hyponatremic alkalosis, increased gastrin production, and malignancy** (Biers et al., 2012)**.**

Contraindications to Augmentation Cystoplasty

Augmentation cystoplasty is contraindicated in patients who have diseases of the bowel (i.e., inflammatory bowel disease, irradiated bowel, short gut syndrome) or bladder pathologic conditions that would preclude using the bladder (Sajadi and Goldman, 2012). Patients or caregivers also must be willing and able to perform CIC for the long term. A patient with a progressive neurologic disease, such as multiple sclerosis, may not have the ability to perform CIC in the future. Noncompliance with CIC puts the patient at risk for life-threatening spontaneous bladder perforation. Renal disease also may be a relative contraindication to augmentation cystoplasty. Baseline renal insufficiency can worsen with the absorption and electrolyte changes that result from exposure of bowel to urine. However, if augmentation cystoplasty is indicated for renal impairment, renal function is expected to stabilize or improve. The series by Ivancić et al. (2010) of pediatric patients with chronic renal insufficiency showed either improvement or no change in renal function after augmentation cystoplasty.

Key Points: Additional Therapies for Storage Failure at the Bladder Level

- The goals of therapy for storage failure are low pressure storage, improved bladder capacity, decreased incontinence resulting from DO, and preservation of renal function.
- Augmentation cystoplasty is an option after failed conservative management such as pharmacologic therapy, intravesical botulinum toxin injection, or CIC.
- Use of large bowel versus small bowel may lead to more significant metabolic disturbance, increased mucus production, and theoretic heightened risk of malignancy.

Additional Therapies for Storage Failure at the Bladder Outlet

The inability to store urine can be the result of an incompetent bladder outlet arising from hypermobility of the urethrovesical junction, intrinsic sphincteric deficiency, denervation of the sphincteric musculature, or frank urethral loss resulting from urethral erosion in women after prolonged urethral catheter use, radiation, or refractory urethral fistulae. The following sections discuss alternative treatments for urine storage failure at the bladder outlet that have not been covered in depth in other chapters in this text.

Urethral Bulking Agents

The goal of injectables is to augment or restore urethral mucosal coaptation and its "hermetic seal effect" contribution to the continence mechanism (Appell and Winters, 2007) **and to maintain coaptation during periods of increased abdominal pressure** (Reynolds and Dmochowski, 2012). **The ideal injectable urethral bulking agent provides luminal coaptation and should be nonantigenic, biocompatible, and cause little or no inflammatory reaction** (Kershen and Atala, 1999) **or fibrotic response** (Dmochowski and Appell, 2000). **It should consist of particles large enough to prevent migration to distant sites (diameter > 80 µm), which are durable enough to produce long-lasting results** (Kirchin et al., 2017). **No material has met all of these requirements.**

Use of Injectable Agents for Female Stress Urinary Incontinence

In the late 1990s injection therapy was the most commonly performed anti-incontinence procedure in women with stress urinary incontinence (SUI), at a rate of 3649 procedures per 100,000 women (Nygaard et al., 2014). By 2007 the rate had fallen to 2236 procedures per 100,000 (Rogo-Gupta et al., 2013). Possible reasons for the decline in numbers include less-than-optimal long-term results and the availability of other minimally invasive options (Kong and Vasavada, 2009).

Table 127.1 lists the bulking agents that are discussed in this section. Collagen was once the most widely used and studied injectable agent, but its production was discontinued in 2010 because of the development of hyaluronic acid fillers. There are currently three FDA-approved urethral bulking agents: Durasphere, Macroplastique, and Coaptite.

TABLE 127.1

Urethral Bulking Agent Materials for Stress Urinary Incontinence

BRAND NAME	MATERIAL	FDA APPROVAL	MAJOR RCT	DISADVAN
CURRENTLY USED				
Durasphere	Carbon-coated zirconium beads	1999	Noninferior to collagen (Lightner et al., 2001)	Particle migratio original formulat (Pannek 2001) Reports periuret mass for (Madjar 2006)
Macroplastique	Silicone microimplants (polydimethylsiloxane)	2006	Noninferior to collagen (Ghoniem et al., 2009)	Requires spe delivery dev (gun)
Coaptite	Calcium hydroxyapatite	2005	Noninferior to collagen (Mayer et al., 2007)	High pa density Reporte vaginal erosion (et al., 20 urethral prolapse al., 2008 et al., 20
Bulkamid	Polyacrylamide hydrogel	Not available in US	Noninferior to collagen (Sokol et al., 2014)	
Urolastic	Polydimethylsiloxane (polymerizes in situ)	Not available in US	No comparative	

			trials Few observational Dutch studies	
NO LONGER USED				
Contigen	Glutaraldehyde cross-linked (GAX) bovine collagen	1993	Lower success rate than surgery (Corcos et al., 2005)	Disconti due to emergen hyaluron fillers (Schwan 2010) Allergic reaction requirin test
N/A	Autologous fat	No	No better than placebo saline (Lee et al., 2001)	Fatal pulmo embolus (Le 2001)
Polytef	Polytetrafluoroethylene	No	No comparative trials	Distant parti migration an granuloma f (Malizia et a
Tegress, Uryx	Ethylene vinyl alcohol	2004	Noninferior to collagen (Karram et al., 2003)	Voluntarily from market high rate (37 urethral eros (Hurtado et 2007)
Zuidex	Dextranomer/hyaluronic acid	No	Midurethral Zuidex inferior to proximal urethral collagen (Lightner et al., 2009)	High rate (1 15%) of pseudoabsce to market withdrawal (Lightner et 2009, 2010)

Urethral bulking agents create artificial urethral cushions to restore urethral mucosal coaptation (Appell and Winters, 2007) **and to maintain continence during periods of increased abdominal pressure** (Reynolds and Dmochowski, 2012). Thus bulking agent injection therapy is well suited for women with intrinsic sphincter dysfunction (ISD). Proper placement of the injectable, just below the bladder neck, rather than actual quantity of the agent (Khullar et al., 1997) improves ISD. **Although initially it was thought that these agents would be most effective in patients with ISD alone, multiple reports have shown clinical efficacy in patients with hypermobility** (Bent et al., 2001a; Herschorn et al., 1996; Lose et al., 2010; Steele et al., 2000).

Patient Selection, Indications, and Contraindications

The American Urological Association (AUA) guideline for surgical treatment of female SUI (http://www.auanet.org/guidelines/stress-urinary-incontinence-(sui)-new-(aua/sufu-guideline-2017) **includes bulking agent therapy as a viable treatment option. However, there are few long-term data with difficulty in measuring long-term outcomes, and inadequate data to recommend one injectable agent over another. The panel recommends that patients should be counseled on the expected need for repeat injections. Bulking agents may still play a role in patients who do not wish to undergo more invasive surgery, who are wishing to avoid a lengthier recovery, or who do not achieve sufficient improvement after a previous anti-incontinence procedure** (Kobashi et al., 2017).

Other considerations may include patients who cannot stop anticoagulation, desire nonsurgical therapy using only local anesthesia, desire more children, have SUI and poor bladder emptying, or have mild SUI associated with exercise (Cespedes and Serkin, 2009).

Contraindications include active urinary infection and hypersensitivity to the injectable material. Caution is warranted in patients with a history of radiation or surgery because severe urethral scarring may affect mucosal pliability by preventing bulking and retention of the injectable in the urethra.

Injection Techniques

Urethral bulking agent injection can be performed using local anesthesia with cystoscopic guidance. **Periurethral** and **transurethral** approaches can be used to implant the agent into the urethral submucosa at the bladder neck or proximal urethra. The technique for injection is shown in Figs. 127.1 and 127.2. The goal is to create mucosal apposition at the end of treatment.

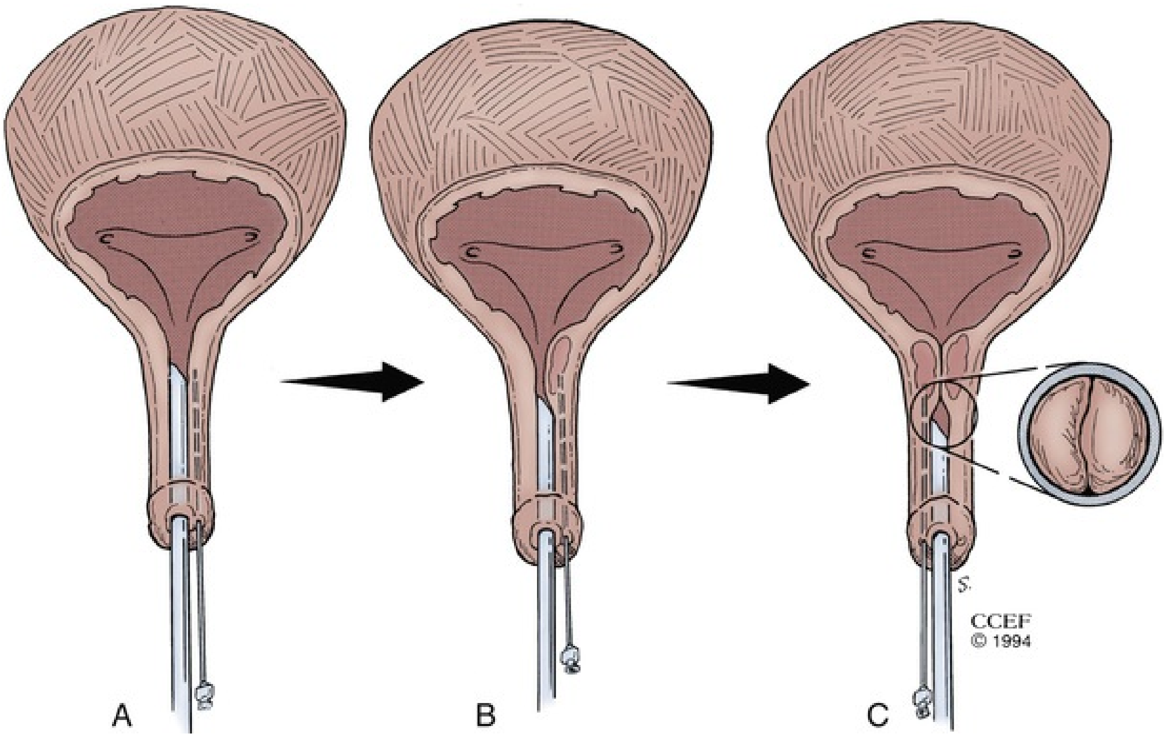

FIG. 127.1 Periurethral collagen injection. The 20-Fr cystoscope with a 30-degree lens is positioned in the urethra while the substance is injected into the bladder neck region. (A) Appearance of the urethra before treatment. (B) Periurethral needle positioned in the proximal urethra below the bladder neck. (C) Appearance of the urethra after injection. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography. Copyright 1994-2011. All rights reserved.)

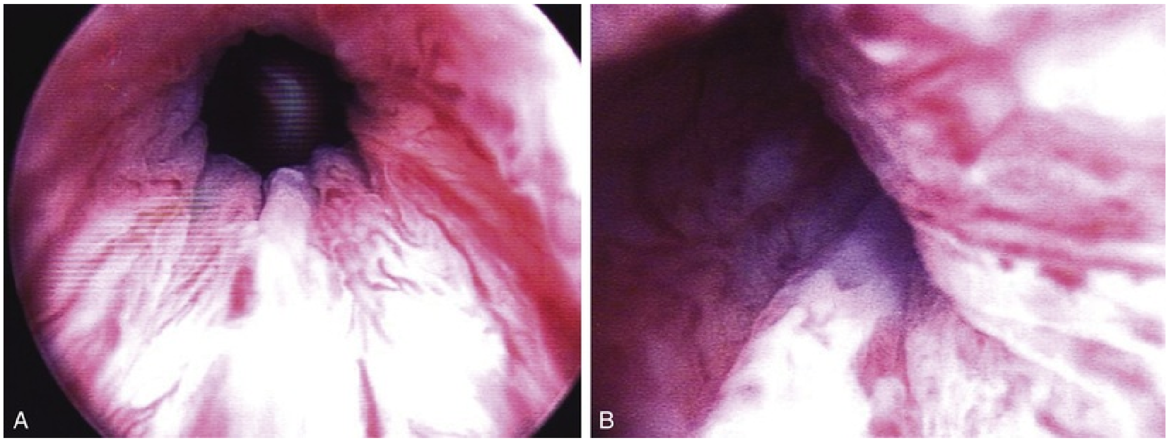

FIG. 127.2 (A) Cystoscopic view of the open bladder neck region before injection. (B) Collagen has been injected via the periurethral route on the patient's left side. Note the intraluminal bulking effect of the bulking agent.

Periurethral Technique.

The patient is placed in the lithotomy position and prepared and draped in the usual sterile fashion. Topical 2% urethral lidocaine jelly is instilled into the meatus. Perimeatal blebs are raised with 1% or 2% aqueous lidocaine approximately 3 to 4 mm lateral to the urethral meatus. A rigid cystoscope with 30-degree lens is inserted into the urethra. The periurethral needle is introduced and advanced parallel to the endoscope sheath until its position can be seen cystoscopically just below the bladder neck within the mucosa. Care must be taken to prevent the needle from entering the urethral lumen and causing extravasation of the agent. If penetration of the mucosa occurs, the needle should be removed and repositioned. The substance is injected either unilaterally or bilaterally to create the appearance of "prostatic" lobes (Fig. 127.3). Transvaginal injection with the needle placed through the biopsy port of an ultrasound probe has also been described (Appell, 1996).

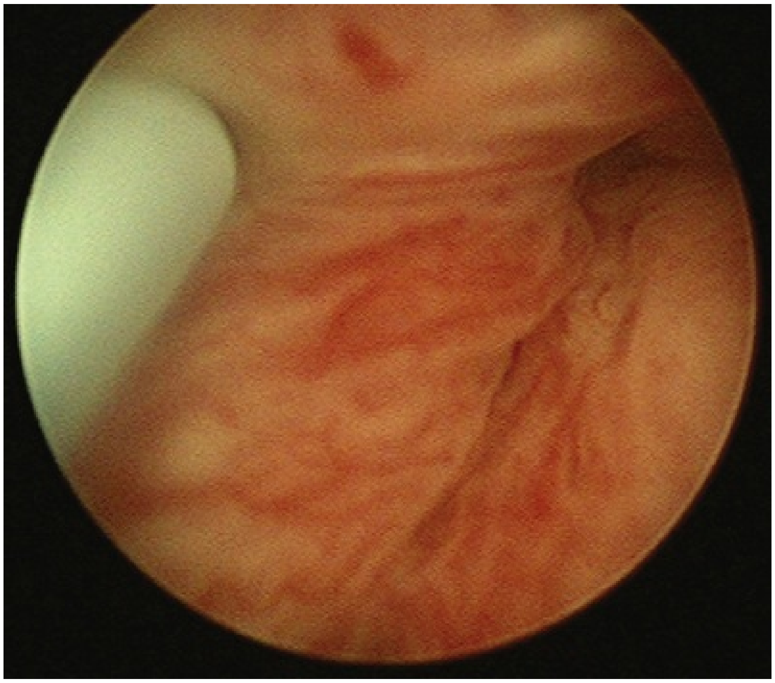

FIG. 127.3 Appearance of urethra after injection of collagen with a transurethral needle, shown on the left. Both sides of the urethra have been injected, giving the appearance of an occlusive prostate.

Transurethral Techniques.

The implant can also be injected transurethrally. The injection needle is inserted through the cystoscope into the urethral mucosa at a 30- to 45-degree angle. The point of penetration of the urethra has to be at a distance below the bladder neck of more than the length of the needle to prevent extravasation of material into the bladder. Injections can be given at the 3-, 6-, and 9-o'clock positions until mucosal apposition is achieved. The cystoscope should not be advanced through the bulked up urethra and bladder neck to avoid compressing or causing extravasation of the injected material.

The periurethral and transurethral approaches for collagen injection were first compared by Faerber et al. (1998), **who reported no significant difference in success rates and numbers of injections required in 24 patients with transurethral treatment versus 21 with a periurethral approach. However, significantly more collagen was required for the periurethral approach. Schulz et al.** (2004) **reported similar findings in 40 women randomly assigned to either technique. Furthermore, the Cochrane review concluded that there are insufficient data to determine whether the transurethral approach is superior to the periurethral approach and whether mid-urethral injection offers any benefit over bladder neck injection** (Kirchin et al., 2017). **The transurethral approach is now more commonly reported than the periurethral approach.**

Periprocedure Care

Postprocedure urinary retention can be treated by insertion of a small caliber Foley catheter (12 to 14 Fr or smaller) overnight or intermittent catheterization. Although not specifically reported, an indwelling Foley catheter may cause molding of the agent and lead to early failure, so long-term catheterization should be avoided.

If stress incontinence persists or recurs after the procedure, reinjection may be performed. The minimum timing for reinjections is variable and depends on the agent. Although bovine glutaraldehyde cross-linked (GAX) collagen (Contigen) could be reinjected within 7 days, most clinicians have waited at least 4 weeks to assess response and the need for reinjection (Appell and Winters, 2007).

Efficacy of Urethral Injection Therapy for Female Stress Urinary Incontinence

The Stamey grading system (0 to 3) (Stamey, 1979) (Table 127.2) for SUI has been recommended as the primary outcome measure by the US Food and Drug

Administration (FDA) since the original US collagen trial (McGuire and Appell, 1994). Although the scale has been used extensively, there is little evidence that it is as valid or reliable as other measures such as voiding diaries, pad tests, and leak point measurements (Payne et al., 2009).

TABLE 127.2

Stamey Incontinence Grading System

GRADE	DESCRIPTION
0	Continent
1	Patient loses urine with sudden increases in abdominal pressure but not when supine
2	Patient loses urine with physical stress (walking; changing from a reclining to a standing position; sitting up in bed)
3	Patient has total incontinence; urine loss unrelated to physical activity and/or position

The Cochrane Database of Systematic Reviews published an updated review of injectable agents in women in 2017 (Kirchin et al., 2017). The authors reviewed the findings of 14 randomized controlled trials (RCTs) including 2004 women and concluded that there are still insufficient data to guide practice. There has only been one placebo-controlled trial comparing autologous fat injection to saline, which demonstrated no difference in cure or improvement between treatment and placebo arms at 3 months (22% vs. 21%, respectively) (Lee et al., 2001). This is likely due to the fact that fat biodegrades rapidly. Because of the lack of efficacy and risk of fatal adverse events (pulmonary fat emboli), autologous fat is no longer used.

Two RCTs demonstrated that injectable therapy had lower success rates than surgical therapy. In one trial comparing collagen versus sling or retropubic suspension, the success rate (dry 24-hour pad test) of collagen injection was significantly lower than surgery at 12 months (53.1% vs. 72.2%, respectively; 95% CI −36.2% to −2%) (Corcos et al., 2005). However, there was no significant difference in satisfaction (67.2% collagen vs. 79.6% surgery, $P = 0.228$), and the patients in the collagen arm had significantly fewer adverse events (36 events in 23 collagen patients vs 84 events in 34 surgery patients, $P = 0.03$). In another trial comparing Macroplastique versus autologous pubovaginal sling in 55 women with ISD, there was a significant difference in objective cure, defined as no leakage resulting from SUI on urodynamics at 6 months (9%

Macroplastique vs 81% surgery, $P < 0.0001$) (Maher et al., 2005). However, there was no significant difference in subjective cure (77% injection vs. 90% sling, $P = 0.41$) or patient satisfaction (60% injection vs. 81% sling, $P = 0.41$). The average cost of Macroplastique (accounting for reinjections) was also found to be more expensive than that of pubovaginal sling ($P < 0.0001$).

Based on the Cochrane analysis, there were no conclusive data to recommend one agent over another based on efficacy; the majority of these trials demonstrated noninferiority of the particular material to collagen (Andersen, 2002; Ghoniem et al., 2009; Lightner et al., 2001; Mayer et al., 2007).

Adverse Events

Common adverse events after urethral bulking agent injection tend to be transient and include urinary retention (0–12%) or elevated postvoid residual (55%–75%), irritative voiding symptoms (17%–46%), hematuria (8%–40%), dysuria (9%–46%), and urinary tract infection (UTI; 0–23%) (Andersen, 2002; Corcos et al., 2005; Ghoniem et al., 2009; Lightner et al., 2001; Maher et al., 2005; Mayer et al., 2007; ter Meulen et al., 2009).

Urethral erosion is a less common adverse event, seen in 1.6% of patients undergoing Macroplastique with collagen in an RCT (Ghoniem et al., 2009). A higher rate (37%) was observed with injection of ethylene vinyl alcohol polymer (Tegress), which was voluntarily removed from the market after initial FDA approval in 2004 (Hurtado et al., 2007).

Particle migration is a possible adverse event, especially when particle size is less than 80 μm. Polytetrafluoroethylene (Teflon) consists of particles 4 to 100 μm and was shown to have distant migration and granulomatous reaction in pelvic lymph nodes, lung, and brain in an animal study (Malizia et al., 1984). The authors concluded that periurethral Teflon injections should not be performed in children or adults of normal life expectancy. Particle migration into urethral mucosa and regional and distant lymph nodes has been demonstrated with the original formulation of Durasphere (200–550 μm) (Pannek et al., 2001). This was subsequently attributed to the high pressure necessary to inject the viscous material with large particles, resulting in material displacement into vascular or lymphatic spaces (Appell et al., 2006).

Summary of Specific Agents

Glutaraldehyde Cross-Linked (GAX) Bovine Collagen (Contigen).

Until it was discontinued in 2010 because of development of hyaluronic acid as an alternative material for cosmetic fillers (Schwanke, 2010), GAX collagen was the most widely used and best-studied urethral injectable agent. It was the standard against which all new injectables were compared.

Contigen was easily injectable through a 22-gauge needle and was supplied in 3-mL syringes. One to three syringes were typically used per treatment. A skin test was required 30 days before treatment because of the 3% rate of allergic reaction.

The use of GAX collagen was first reported by Shortliffe et al. (1989), and since then, there have been numerous reports of its efficacy, safety, ease of administration, and relative lack of morbidity (Corcos and Fournier, 1999; Cross et al., 1998; Gorton et al., 1999; Herschorn et al., 1992; Khullar et al., 1997; Winters and Appell, 1995). Herschorn and Radomski (1997) performed a Kaplan-Meier analysis showing that the probability of remaining dry after the last collagen injection was 72% at 1 year, 57% at 2 years, and 45% at 3 years (Fig. 127.4). Most patients needed one or two treatment sessions with a mean of 5.6 to 15 mL of collagen.

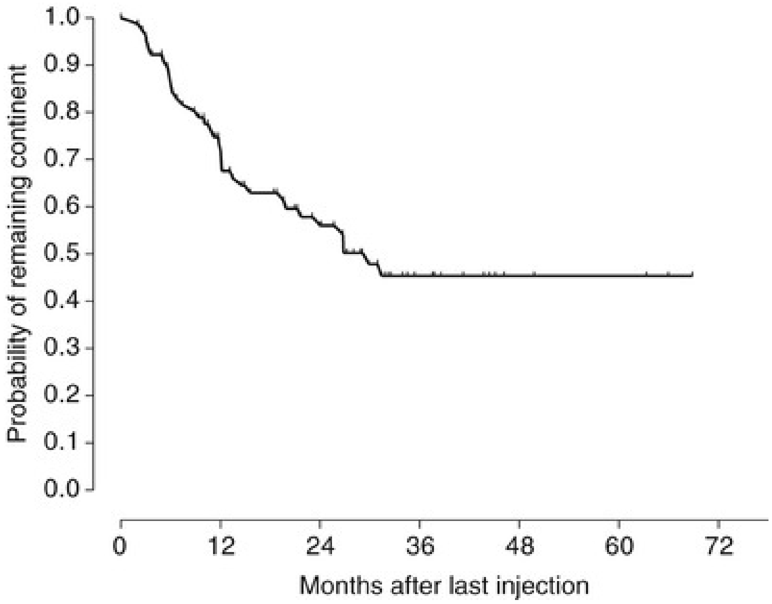

FIG. 127.4 Durability: Kaplan-Meier curve showing durability of cure of incontinence after the last collagen injection in 78 patients. (From Herschorn S, Radomski SB: Collagen injections for genuine stress urinary incontinence: patient selection and durability. *Int Urogynecol J Pelvic Floor Dysfunct* 8[1]:18–24, 1997.)

Carbon-Coated Zirconium Beads (Durasphere).

Durasphere consists of pyrolytic carbon-coated zirconium beads suspended in 2.8% glucan. The original formulation of Durasphere was highly viscous (particle size 200–550 µm) and required high pressure to inject. Durasphere-EXP was later introduced to address this issue, with particle size 95 to 200 µm.

In the original multicenter randomized 235-patient clinical trial of Durasphere versus collagen, Lightner et al. (2001) reported similar 12-month continence grade improvement rates between the two agents (66.1% Durasphere vs. 65.8% collagen, $P = 1.000$). However, the injected initial and repeat injection volumes of Durasphere were significantly less than those of collagen. Another RCT by Andersen (2002) demonstrated similar results: 80% (20 of 25) of Durasphere patients versus 61.9% (13 of 21) of collagen patients had a continence grade improvement ($P = 0.205$) after a mean of 2.6 and 2.8 years, respectively.

Rare but reported adverse events include urethral mucosal prolapse (Ghoniem and Khater, 2006), periurethral mass formation requiring drainage in 2.9% in a series of 135 patients (Madjar et al., 2006), and a pseudoabscess found 5 years after injection (Berger and Morgan, 2012).

Silicone Microimplants (Macroplastique).

Macroplastique consists of solid polydimethylsiloxane particles suspended in inert bio-excretable gel. Because of its high viscosity, injection of Macroplastique requires the use of a ratcheted injection gun (Fig. 127.5).

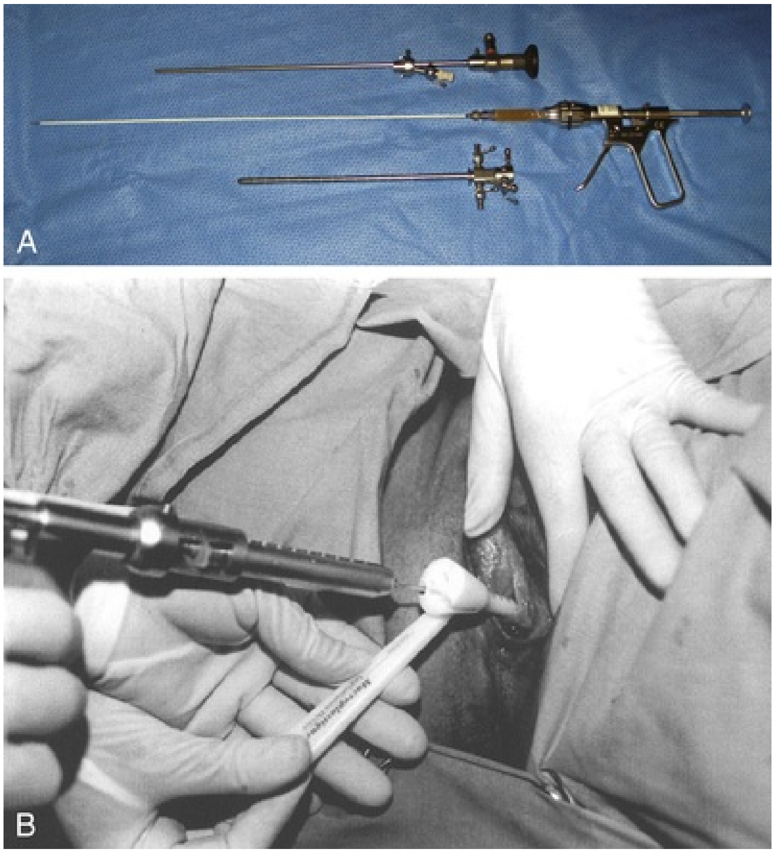

FIG. 127.5 (A) Silicone macroparticle injection gun. The injection needle is 7 Fr with a 10-mm, 18-gauge needle tip. (B) The implantation procedure. The bulking agent is injected through the device using the injection gun and a rigid needle. (From Tamanini JT, D'Ancona CA, Netto NR Jr: Treatment of intrinsic sphincter deficiency using the Macroplastique Implantation System: two-year follow-up. *J Endourol* 18[9]:906–911, 2004.)

A systematic review and meta-analysis of Macroplastique series from 1990 to 2010 was reported by Ghoniem and Miller (2013)**. The authors included 24 published articles with a total of 958 patients. Short-term (<6 months) cure and improvement rates were 43% and 75%, respectively. Medium-term (6 to 18 months) rates were 37% and 73%. Long-term (>18 months) rates were 36% and 64%. The median reinjection rate was 30%, and higher reinjection rates resulted in improved long-term outcomes.**

In a multicenter randomized trial of Macroplastique versus collagen in 247 women with ISD, Macroplastique was shown to have a significantly higher cure rate (36.9% vs. 24.8%, $P < 0.05$) (Ghoniem et al., 2009). However, there were no significant differences in pad weight testing, quality-of-life scale, or adverse events. The same authors subsequently reported follow-up results in the Macroplastique patients who had successful outcome at 12 months, showing

84% sustained success at 24 months (Ghoniem et al., 2010). Another RCT demonstrated Macroplastique injection to be superior to pelvic floor exercises in patients with SUI and urethral hypermobility (ter Meulen et al., 2009).

The systematic review by Ghoniem and Miller (2013) noted the absence of any serious reported adverse events over the 20 years of global experience.

Calcium Hydroxylapatite (Coaptite).

Coaptite consists of calcium hydroxylapatite (CaHA) particles in a carboxymethylcellulose gel carrier (Mayer et al., 2007). Calcium hydroxylapatite is a normal constituent of bone and thus nonimmunogenic. Coaptite is more viscous than collagen; it is currently supplied in 1-mL syringes and can be injected via a transurethral approach through a 21-gauge needle.

In a randomized prospective trial of CaHA versus collagen in 231 women with ISD only and 12-month follow-up, Mayer et al. (2007) demonstrated no significant difference in the primary outcome measure: improvement of at least one Stamey grade in 63.4% of CaHA patients versus 57% ($P = 0.34$). There was also no difference in overall cure rate (39% CaHA vs. 37% collagen, $P = 0.78$). However, more CaHA patients required only one injection, and the total average injected volume was lower (4.0 mL vs. 6.6 mL respectively; $P < 0.0001$).

Overall, CaHA was shown to have a similar safety profile to collagen (Mayer et al., 2007). Rare complications include vaginal wall erosion, dissection of the material beneath the trigone (Mayer et al., 2007), urethral mucosal prolapse (Lai et al., 2008; Palma et al., 2006), and injection site granuloma (Gafni-Kane and Sand, 2011).

Agents Available Outside the United States.

Bulkamid (polyacrylamide hydrogel) and Urolastic (polydimethylsiloxane [PDMS-U]) are currently used injectable agents found in Europe and are mentioned in Table 127.1.

Adjustable Continence Therapy

The Adjustable Continence Therapy (ACT) device was developed as an alternative to bulking agents that would not migrate (Kocjancic et al., 2008). It consists of two inflatable silicone balloons attached to silicone tubing with a titanium and silicone port (Fig. 127.6). The procedure can be done using local, regional, or general anesthesia. The balloons are placed into the periurethral space at the bladder neck with introducer devices inserted through 1-cm incisions in the labial sulci. The procedure is carried out under fluoroscopic guidance with a contrast-filled Foley balloon positioned at the bladder neck. After the correct position is ascertained, the device balloons are inflated with 1 to 1.5 mL of an isotonic solution (sterile water and contrast material). The aim is to increase urethral resistance and support the bladder neck with the inflated balloons (Stecco et al., 2006). The ports are buried in the subcutaneous tissue of the labia to enable postoperative reinjection of the balloons if necessary (Kocjancic et al., 2008). Beginning at 6 weeks, additional fluid, usually in increments of 2 mL, can be added to the balloons by percutaneous injection through the port sites. Each balloon has a capacity of 8 mL.

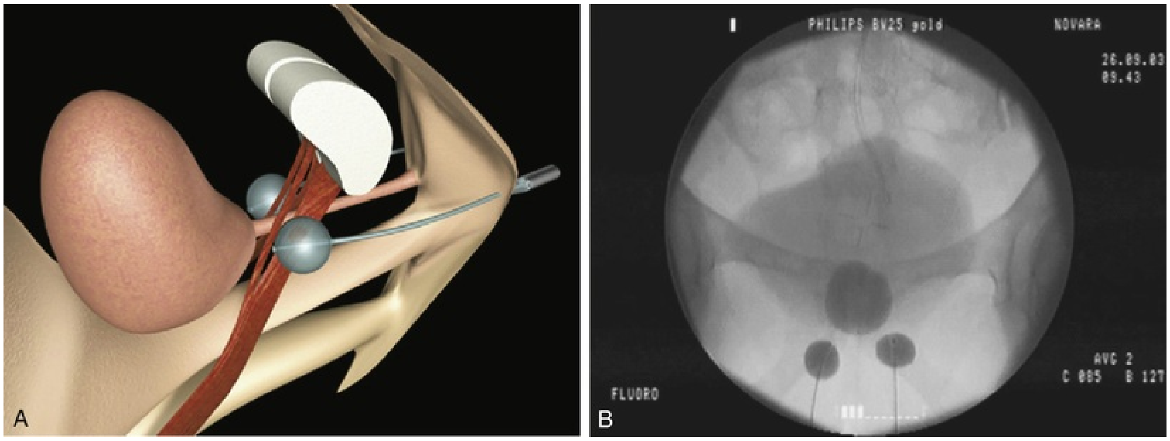

FIG. 127.6 Illustration of Adjustable Continence Therapy balloon device for women. (A) Schematic diagram showing percutaneous placement of the balloons on both sides of the bladder neck. (B) Fluoroscopic picture showing contrast agent in the bladder, Foley catheter, and balloons. (From Aboseif SR, Franke EI, Nash SD, et al.: The Adjustable Continence Therapy system for recurrent female stress urinary incontinence: 1-year results of the North America Clinical Study Group. *J Urol* 2009;181[5]:2187–91.)

Outcomes

Use of ACT in female patients with SUI was first reported in a prospective study by Chartier-Kastler et al. (2007). Of the 29 women followed for a mean of 2 years, 87% were dry or improved. There have been several studies on the use of ACT in recurrent SUI after anti-incontinence procedures, demonstrating dry rate of 44% to 68% (Cross et al., 1998; Gorton et al., 1999; Kocjancic et al., 2008;

Wachter et al., 2008). The longest term results were reported by Kocjancic et al. (2010). In 29 patients with a mean follow-up of 6 years, 68% considered themselves dry. On the Patient Global Impression of Improvement questionnaire, 64% of patients rated their symptoms as very much improved, 23% as much improved, and 13% as minimally improved or unchanged.

Rate of balloon adjustment has been reported as 62% to 69% (Kocjancic et al., 2008; Wachter et al., 2008), and Aboseif et al. (2009) reported a mean of 2.3 balloon adjustments per patient within the first 9 months.

There has been one comparative study on ACT. A French retrospective study compared outcomes of ACT versus artificial urinary sphincter (AUS) placement in 61 patients with SUI resulting from ISD (Freton et al., 2018). At baseline, the patients in the ACT group were older and had more comorbidities. The AUS group had better functional outcomes (dry rate 71.4% AUS vs. 21.7% ACT, $P < 0.001$), but a higher rate of intraoperative complications, longer operative time, and longer hospital stay.

Similar to urethral bulking agents, ACT may represent a reasonable option for treatment of SUI in patients who have recurrent SUI after anti-incontinence procedures as well as in older patients who may not be candidates for more invasive procedures.

Complications

The complication rate has been reported to be 24% (Aboseif et al., 2009) to 39% (Wachter et al., 2008), with most classified as mild to moderate. Reported intraoperative perforation rates are 3.7% to 45% (Phe et al., 2014). During the first year postoperatively, reported complications include balloon migration (6.5% to 17.5%) or dysfunction (0.6% to 8.9%), urethral erosion (2% to 15%), cutaneous erosion of the port (3% to 75%), device infection (0.6% to 6%), treatment failure or worsening of incontinence (2.5% to 11.7%), dysuria or retention (1.5% to 6.8%), and de novo urgency (10.5%) (Phe et al., 2014).

The explantation rate is 15% to 38% (Chartier-Kastler et al., 2007; Phe et al., 2014). The reimplantation rate is up to 50% in various studies (Phe et al., 2014).

Cell-Based Therapy

Cell-based therapy for SUI represents a new frontier in regenerative medicine. Autologous stem cells can be injected into the urethral sphincter with the goal of regenerating deficient anatomic components of the urethral continence mechanism. Stem cell therapy has the potential to restore the external (striated muscle) and internal (smooth muscle) urethral sphincter, neuromuscular synapse, and blood supply (Hart et al., 2015). Because of its mechanism, this therapy is thought to be best suited for patients with ISD. As of 2017, the AUA guideline mentions stem cell therapy as a potential future option for treatment of female SUI but states it should not be offered outside of investigational protocols (Kobashi et al., 2017). Advantages of cell-based therapy for SUI include treatment of the cause rather than just the symptom as well as lack of immunologic reaction with the use of autologous cells. In addition, needle biopsy and urethral injection can be performed in a minimally invasive fashion under local anesthesia.

The use of adult stem cells derived from skeletal muscle, bone marrow, umbilical cord, and adipose tissue has been investigated in animal and human studies (Williams et al., 2016). The majority of clinical trials have involved autologous muscle-derived cells (AMDCs).

Human Studies

In their pilot North American study, Carr et al. (2008) reported on their 1-year experience with urethral injection of AMDCs ($18–22 \times 10^6$) isolated from quadriceps biopsies in 8 women with SUI. Clinical improvement was reported in 5 of 8 women; one achieved complete continence. Onset of improvement was seen between 3 and 8 months after injection, with sustained improvement at a median of 10 months. In the subsequent prospective dose ranging study, 38 women underwent periurethral injection of low ($1, 2, 4, 8$, of 16×10^6) or high doses ($32, 64$, or 128×10^6) of AMDCs with promising results (Carr et al., 2013). In the high-dose group, a higher percentage of patients experienced 50% or greater reduction in pad weight (88.9% high dose vs. 61.5% low dose), 50% or greater reduction in diary-reported stress leaks (77.8% vs. 53.3%), and had 0 to 1 leak in a 3-day period (88.9% vs. 33.3%) at 12-month follow-up.

Peters et al. (2014) reported the safety and 12-month efficacy outcomes of two pooled phase II studies of AMDCs using four increasing doses ($10, 50, 100$, and 200×10^6). They also found that higher-dose groups tended to have greater percentages of patients with at least a 50% reduction in stress leaks and pad weight. All groups had statistically significant improvements in Urogenital Distress Inventory-6 and IIQ-7 scores.

Randomized controlled trials on use of AMDCs for urinary sphincter repair have yet to be published. Preliminary data from a Phase III double-blind RCT in 143 women with SUI (50 placebo, 93 AMDCs at dose 150×10^6) were recently presented (Carr et al., 2017). The patients were randomized 2 : 1 to receive intrasphincteric injection at a dose of 150×10^6 or placebo, and within the treatment group, randomized 1 : 1 to receive 1 versus 2 treatments (second treatment being performed at 6 months). At 12 months, all patients were unblinded, and those receiving placebo could opt to receive AMDC injection. With their preliminary data, the authors concluded that AMDCs may provide durable reduction in incontinence episode frequency (IEF). The aforementioned studies were sponsored by Cook Myosite, Incorporated (Pittsburgh, PA).

Additional studies using AMDCs have shown promising results. Mitterberger et al. (2007) reported on 123 women with SUI who underwent transurethral ultrasound (TUUS)–guided injection of autologous fibroblasts into the urethral submucosa and myoblasts into the rhabdosphincter, using cells cultured from biceps biopsies. One year after therapy, 94 women (79%) were cured, 16 (13%) were substantially improved, and 9 (7%) were slightly improved; 4 were lost to follow-up. TUUS and electromyography evaluation demonstrated significant improvement in thickness and contractility of the rhabdosphincter. Stangel-Wojcikiewicz et al. (2014) reported 2-year outcomes of transurethral sphincter injections of autologous muscle-derived stem cells (MDSCs) harvested from the deltoid in 16 women with SUI. After 2 years, 8 (50%) were dry and an additional 4 (25%) were improved; in 4, the treatment failed. The authors noted that the mean time for initial improvement was 4.7 months. They also noted that success was seen with a relatively small number of cells ($0.6 – 25 \times 10^6$). Cornu et al. (2014) reported the long-term outcome of autologous MDSC injection in 12 women, 11 of whom had recurrent SUI after anti-incontinence procedures. Of the 2 patients who were dry at 1 year, both were still dry at 6 years. Of the 5 who were considered improved at 1 year, all worsened, but 3 remained satisfied. There were 5 failures.

To avoid the need for expensive cell preparation technology, Gras et al. (2014) tested the effect of intraurethral injection of minced autologous skeletal muscle tissue in 20 women with uncomplicated and 15 with complicated SUI. After 12 months, cure and improvement were noted in 25% and 63% of the uncomplicated group and 7% and 57% of the complicated group, respectively. The results appear similar to reports with harvested stem cells.

In Phase II trials, there were no serious adverse events (Peters et al., 2014). There were biopsy-related adverse events in 4 patients: wound hematoma (2), procedural dizziness (2), postoperative bleeding requiring sutures (1), and joint swelling (1). Injection–procedure-related adverse events occurred in 18% (14 of 80): dysuria (7), pelvic/abdominal pain (4), vulvovaginal pruritus (3), urinary urgency (2), and transient hematuria (2). There were no reports of urinary retention, which distinguishes this therapy from existing procedures for SUI.

Other cell types have also been studied. The first human study of cell therapy for SUI involved injecting autologous ear chondrocytes as a urethral bulking agent in 32 women (Bent et al., 2001b). After 1 year, 81% were improved and 50% were dry. Lee et al. (2010) reported the outcome of transurethral injection of a 2-mL suspension of umbilical cord blood stem cells in 36 women. After 12 months, 26 (72.2%) were cured or improved, and in 10 (27.8%), the procedure failed. In a study using autologous adipose derived cells in 5 females with SUI, one patient was continent at 6 months and an additional 2 were continent at 12 months; the authors used the cough test as their primary end point (Kuismanen et al., 2014). **The technology looks promising and may provide advantages over bulking agents. However, there are no large or comparative studies, and no long-term data are available yet. Furthermore, the ultimate cost of the technology will determine whether it becomes a feasible alternative.**

Use of Injectable Agents for Male Stress Urinary Incontinence

Urethral bulking agents may also be used to treat male patients with SUI, the majority of whom have postprostatectomy incontinence (PPI). **Several agents have been used including bovine collagen (Contigen) and silicone microparticles (Macroplastique). All agents share similar problems including the need for multiple injections, deterioration of effect over time, and low cure rates.**

Evaluation of postprostatectomy patients is discussed in detail in Chapter 131. **Before bulking agent injection, cystourethroscopy is recommended to verify integrity of the urethral wall and bladder neck and the status of the bladder (e.g., trabeculation, stones, diverticula). Injectables are not effective with scarred supramembranous urethras because the tissues cannot expand with the agent.**

Injection Techniques

Retrograde Injection.

Urethral bulking agent injection may be performed transurethrally under cystoscopic guidance using local, regional, or general anesthesia (Fig. 127.7A). A 20- or 22-Fr cystoscope sheath is used with a 0-degree or 30-degree lens. The needle is advanced under the urethral mucosa with the beveled portion facing the urethral lumen to allow for layering of the material. The injectable material is then delivered, creating a bleb under the urethral mucosa that protrudes into the urethral lumen. This is performed in a circumferential manner in four quadrants. After completion, the urethral mucosa should be completely coapted, creating the appearance of an obstructed urethra. The postprostatectomy urethra is frequently scarred and not very pliable; thus several needle insertions may be needed to deposit sufficient material for urethral coaptation. Extrusion of the injectable agent into the urethral lumen may be prevented by leaving the needle in place for at least 30 seconds or by flushing the material with saline. The loss of additional material is diminished by preventing advancement of the cystoscope proximal to the injection sites.

(B) Antegrade urethral technique injection in the male after radical prostatectomy. (A, Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography. Copyright 1994–2011. All rights reserved.)

Antegrade Injection.

Because of less-than-optimal results, an alternative method of injecting collagen in men was introduced, involving a suprapubic antegrade approach. The antegrade approach has the advantage of direct visualization of the bladder neck and the injection of material into a more supple, less scarred urethra (Fig. 127.7B). The patient is placed in the lithotomy position and flexible cystoscopy is carried out, simultaneously filling the bladder. A percutaneous suprapubic puncture allows placement of two guidewires into the bladder. The site is dilated to 16 Fr with Amplatz dilators. A sheath may be used, but commonly the cystoscope (flexible or rigid pediatric) can be advanced over one of the guidewires into the bladder. A small red rubber catheter or the flexible cystoscope can be used to assist in localization of the bladder neck. The needle is placed just under the urethral mucosa at the level of the bladder neck and advanced proximally, meaning it is pulled back toward the bladder. The bladder neck closes off completely as the material is injected on either side. A small suprapubic tube (SPT) can be placed to avoid the possible necessity of urethral catheterization.

Collagen.

For collagen, success rates for PPI range from 36% to 69%, with 4% to 20% of patients reporting being dry (Aboseif et al., 1996; Cespedes et al., 1999; Cummings et al., 1996; Klutke et al., 1999; McGuire and Appell, 1994; Sanchez-Ortiz et al., 1997; Smith et al., 1998a; Tiguert et al., 1999). Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections are required to achieve modest rates of subjective improvement. There is no advantage of delivery technique (retrograde vs. antegrade).

Collagen injection does not adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate (Gomes et al., 2000), nor does it adversely affect outcomes of bone-anchored male sling placement (Comiter, 2002; Onur and Singla, 2006).

Silicone Microimplants (Macroplastique).

Use of Macroplastique in PPI was first reported by Colombo et al. (1997), who followed 6 men for a mean of 15.5 months. Of 6 patients, 5 became dry and 1 was substantially improved. Although initial success has been demonstrated, results have been shown to deteriorate over time (Bugel et al., 1999; Kylmala et al., 2003).

In a randomized trial of AUS implantation versus Macroplastique injection, Imamoglu et al. (2005) demonstrated no difference in success with AUS versus Macroplastique in men with mild incontinence (the vast majority had SUI after benign prostatic hyperplasia [BPH] surgery, with more than one-third of the cohort having SUI after open radical prostatectomy). However, in patients with more severe incontinence, the AUS was superior, with minimal improvement seen after transurethral Macroplastique.

Cell-Based Therapy.

Use of autologous muscle-derived cells has also been studied in male patients with postprostatectomy SUI. Mitterberger et al. (2008) injected autologous fibroblasts and myoblasts into the rhabdosphincter of 63 patients with postprostatectomy SUI. The authors reported continence in 41 of 63 patients, improvement in 17, and lack of improvement in 5, as well as improvements in thickness and contractility of the rhabdosphincter on transurethral ultrasound. In a study of 222 patients undergoing transurethral injection of AMDCs with at least 12-month follow-up, 12% were continent, 42% showed improvement, and in 46%, therapy was ineffective (Gerullis et al., 2012). There have been 3 trials on autologous adipose-derived regenerative cells (ADRCs) in a total of 20 males with incontinence after prostate surgery (Choi et al., 2016; Gotoh et al., 2014; Yamamoto et al., 2012). In the largest of these studies ($n = 11$) with 1 year follow-up, 8 patients demonstrated progressive improvement in SUI and 1 achieved total continence (Gotoh et al., 2014). Also, enhanced ultrasonography showed a progressive increase in blood flow at the area of injection, suggesting an angiogenesis effect.

Use of Injectable Agents After Urinary Diversion

There are increasing numbers of reports in the literature about the use of injectables after diversion. In a canine study, Izes et al. (1997) demonstrated that GAX collagen injected circumferentially into the lumen of the ileocecal valve can increase the leak point pressure for up to 1 month. Subsequently, Smith et al. (1998b) reported results of collagen use in 6 patients with incontinence after Indiana pouch; 5 of 6 remained dry after a mean follow-up of 26 months.

Macroplastique has also been used for treatment of incontinent catheterizable channels. Guys et al. (2002) reported on the use of Macroplastique in 6 patients (4 appendix and 2 ileum) with a mean of 6 (3 to 8) mL. One had a second injection after 3 months. Four of 6 were continent after a mean of 11 (8 to 18) months. Halachmi et al. (2004) reported cure in 3, improvement in 1, and no change in 1 of 5 patients with stoma leakage. Kass-Ilya et al. (2015) reported a 50% success rate in 24 patients after a mean of 30 months. Three were dry and 9 were improved. Five of the 9 improved patients went on to surgery at a mean of 41 months.

Prieto et al. (2006) treated 14 patients with leaking stomas with 2 to 6 mL (mean 3.7 mL) of dextranomer/hyaluronic acid (DHA). With a mean follow-up of 1 year, 10 were dry after one injection, 1 was dry after two injections, and 3 had treatment failure. Welk et al. (2008) achieved success in 2 of 4 patients with DHA injections. Injectable agents appear to be a benefit for stomal incontinence in more than 50% of reported patients and may obviate or delay surgical revision.

Injectables have been reported in women with urethral incontinence after neobladder construction. Tchetgen et al. (2001) reported on 3 women with SUI after cystectomy and orthotopic neobladder. An average of two collagen injections were given, with a cure in 1 patient, improvement in 1, and no change in 1. Wilson et al. (2004) administered transurethral collagen to 11 patients and Durasphere to 1 patient with SUI after cystectomy and neobladder. After a mean of 22.5 months, 2 patients (16.7%) were dry, although they continued to have urinary frequency. Four patients (33.3%) were improved and 6 were unchanged. The authors concluded that the treatment response was not optimal or durable.

New-onset vesicovaginal fistula was reported in two patients who had undergone collagen injection for SUI after cystectomy and neobladder (Pruthi et al., 2000). Both patients underwent transvaginal fistula repair with pubovaginal sling.

Bladder Outlet Closure: Functional and Complete

In certain instances, when other surgical interventions have failed, urethral or bladder neck closure is necessary to treat refractory incontinence resulting from urethral erosion, severe stress incontinence, bladder neck incompetence, or difficult urethral fistulae. One familiar clinical scenario is that of a neurogenic female patient managed with a long-term indwelling urethral catheter. Over time, the catheter balloon causes pressure necrosis and urethral/bladder neck destruction, leaving a very patulous, incompetent urethra. Chancellor et al. (1994c) reported their results with **functional bladder neck closure using an obstructing autologous pubovaginal sling** in 14 female patients with neurogenic, end-stage bladders and a destroyed bladder outlet from chronic indwelling Foley use. All women had an intact bladder neck and at least 1 cm of viable proximal urethra. With a mean follow-up of 24 months, all patients had success with minimal incontinence and a low rate of complications. **This type of functional bladder neck closure avoids complete closure of the urinary system, providing a "pop-off" valve for leakage at higher pressures and allows access for possible future instrumentation.** In this type of scenario, in which the sling is meant to obstruct the bladder outlet, autologous or cadaveric slings are superior to mesh slings, which would be much more likely to erode into the urethra. However, several studies have described using mesh slings in a "spiral" fashion to wrap the urethra circumferentially for refractory patients with stress urinary incontinence (Mourtzinos et al., 2008; Rodriguez et al., 2010; Rutman et al., 2006). This technique, first described by Rutman et al. (2006), involves a transvaginal urethrolysis to gain access to the urethra circumferentially. A polypropylene mesh sling with sutures attached to each of the ends is completely wrapped around the urethra, crossing at the ventral urethra, and then the ends are passed retropubically and tied above the fascia. Success of 72% to 87%, or overall improvement in symptoms, was reported in these small series with few complications noted (Mourtzinos et al., 2008; Rodriguez et al., 2010; Rutman et al., 2006).

When preservation of a functional bladder outlet is not a viable option, transvaginal, transabdominal (retropubic), or combined bladder neck closure along with LUT reconstruction to the abdominal wall is indicated. **Closure of the bladder neck is more challenging than a simple cystorrhaphy. The bladder neck is hyperactive in neurogenic patients, and stress is placed on the bladder neck closure with every voiding reflex.** It is imperative to have a multilayer, watertight closure and use postoperative drains to avoid fistula formation (Fig. 127.8). In addition, an adequate time of continuous bladder drainage and use of anticholinergics will limit the stress on the bladder neck suture line.

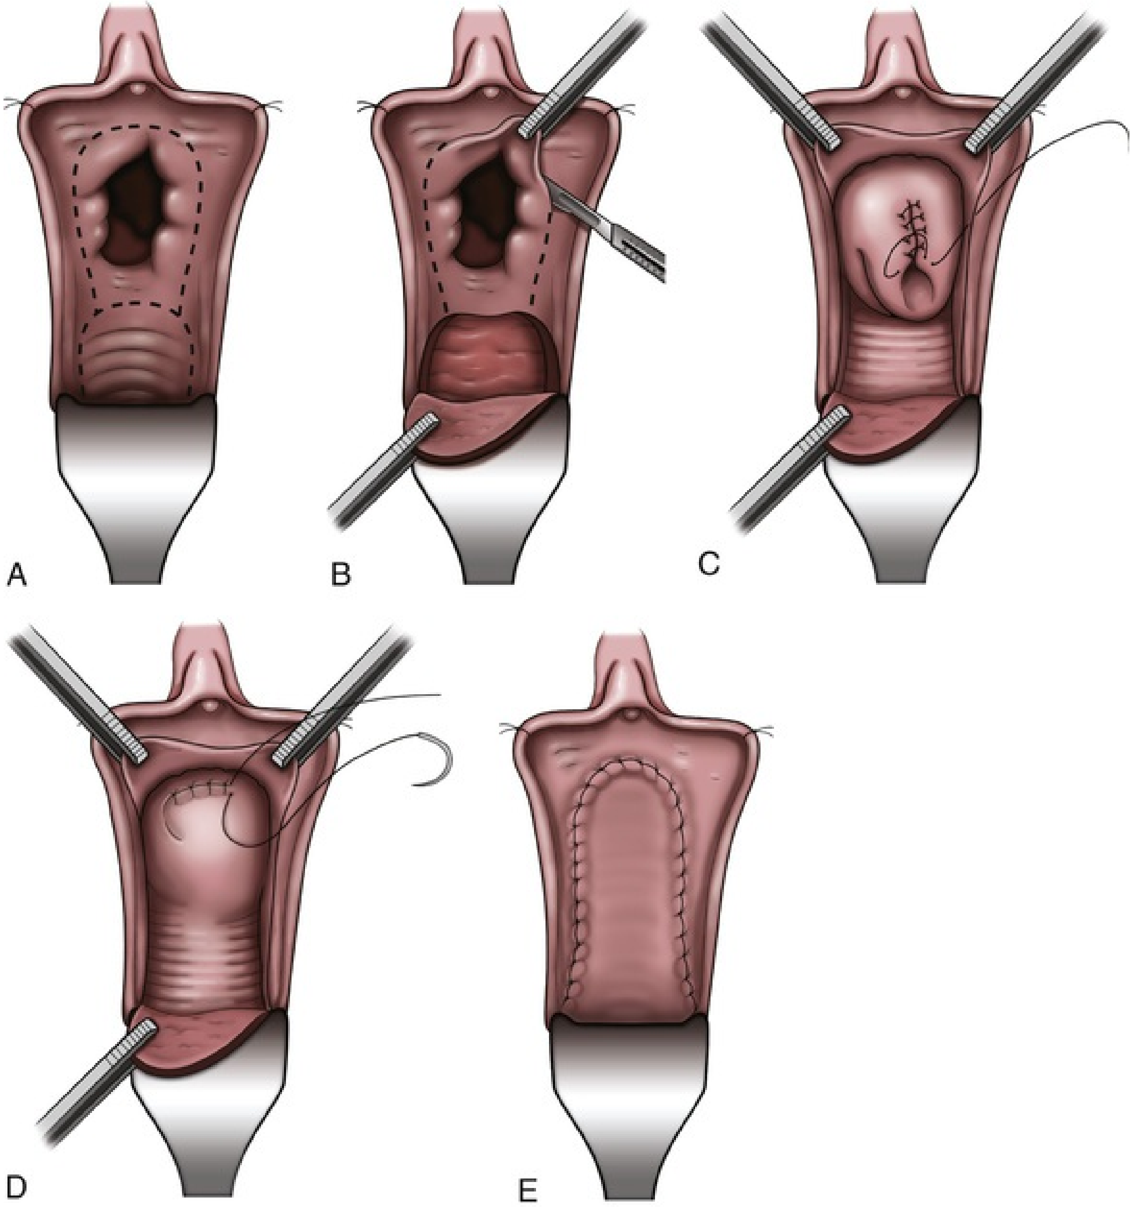

FIG. 127.8 (A) After injection of normal saline solution into the anterior vaginal wall, an incision is made around the urethral opening to create the vaginal wall flap. (B) The urethral meatus is dissected free, and the vaginal wall flap is created. (C) The bladder neck wall musculature is vertically closed in a running fashion after the mucosal layer has a watertight closure. (D) The final muscular layer is closed in a horizontal fashion and rotated superiorly behind the pubis. (E) The vaginal epithelium is advanced over the entire defect and closed with a running suture.

Levy et al. (1994) reported a 40% success rate using a transvaginal bladder neck closure. They subsequently modified the approach, using a combined transvaginal-transabdominal approach and reported a 100% success rate at a mean 16-month follow-up for the subsequent 10 patients. Shpall and Ginsberg (2004) reported on 39 patients who underwent a combined transabdominal bladder neck closure and various continent and incontinent diversions. At a mean of 37 months, 6 patients (15%) developed fistulae; however, 4 patients underwent successful repair for an overall 95% cure rate. In addition, O'Connor et al. (2005) reported on 35 patients with a mean 79-month follow-up who underwent a transabdominal bladder neck closure for refractory incontinence. They were initially successful in 28 (83%) patients, with an overall 94% cure rate after one revision. Most recently, Kavanagh et al. (2012) reported with a median follow-up of 69 months on 28 pediatric or adolescent patients who underwent concomitant transabdominal bladder neck closure with enterocystoplasty and Mitrofanoff diversion. Bladder neck closure was successful in 96.4% of patients, with only one requiring repair of a postoperative vesicovaginal fistula. In addition, there was no evidence of progressive or new hydronephrosis in their cohort. **Ultimately, closure of the bladder outlet with simultaneous LUT reconstruction is often required and can be highly successful in certain refractory patients who have failed other surgical treatments for their destroyed bladder outlet.**

In a retrospective study of 64 patients, transvaginal and transabdominal (retropubic) approaches were shown to have similar urethral continence rates (85.7% transvaginal vs. 81.5% retropubic, $P = 0.74$) (Willis et al., 2015). However, transvaginal bladder neck closure was associated with shorter operative time, decreased length of hospital stay, and fewer short-term complications.

Bladder neck closure is definitive, and patients need to understand the importance of adhering to consistent bladder drainage to avoid the complication of spontaneous bladder perforation. Although rare, concerns also arise over the potential difficulty in accessing the bladder acutely because of an emergency situation or possible stomal stenosis; reported rates of stenosis are 6% to 19.5% (Ardelt et al., 2012; Leslie et al., 2011; Welk et al., 2008). One group discusses equipping all their patients with MedicAlert bracelets and instructing them on how to decompress their bladder if need be via percutaneous needle aspiration (Kavanagh et al., 2012).

Key Points: Additional Therapies for Storage Failure at the Bladder Outlet

- Goal of urethral injection therapy is to restore urethral mucosal coaptation and its hermetic seal effect, especially during periods of increased abdominal pressure.
- Injectable agents are an option for patients who are not candidates for more invasive procedures. Efficacy and durability are generally inferior to surgery.
- Functional urethral closure with pubovaginal sling provides pop-off valve for leakage at higher pressures and allows access for transurethral instrumentation.
- Bladder neck closure with simultaneous LUT reconstruction may be successful in refractory patients with destroyed bladder outlet.

Additional Therapies for Emptying

Continent Catheterizable Channels

Some neurogenic patients require CIC to empty but have difficulty accessing the native urethra. This can be the case in patients with limited upper extremity dexterity or in patients who are wheelchair-bound and find it troublesome to position themselves for CIC. Often these patients depend on caregivers to assist them with CIC, have impaired self-esteem and body image, and ultimately desire more independence. Walsh et al. (2004) studied quadriplegic female patients who underwent surgery for creation of continent catheterizable channels. The authors show that these patients had significant improvements in quality-of-life measures and had increased efficiency in catheterizing (decrease in time to catheterize from 27 [range 10 to 40] to 7.8 [range 1 to 15] minutes). Another study by Zommick et al. (2003) reviewed outcomes of continent LUT reconstruction in 21 patients with cervical SCI and varying degrees of upper extremity dexterity. These patients reported improvements in quality of life because of eradication of urinary drainage bags, increased continence, more freedom, and improved body image. In addition, a majority (95%) were able to maintain CIC long term by themselves or with the help of a caregiver. Furthermore, neurogenic patients undergoing augmentation cystoplasty who also have severe incontinence resulting from urethral erosion or bladder neck incompetence may benefit from concomitant bladder outlet surgery and formation of a continent catherizable channel at the time of LUT reconstruction.

Urethral loss also can necessitate creation of a continent catheterizable channel to maintain bladder access and continence. **In addition to neurogenic patients, patients with non-neurogenic benign disease processes such as recalcitrant bladder neck contracture, urethral loss from stricture or radiation damage, and refractory urethral fistulae are candidates for continent LUT reconstruction.**

Various techniques, many using the flap-valve mechanism for continence, have been described: the Mitrofanoff appendicovesicostomy (Mitrofanoff, 1980); a transverse ileal tube (Yang-Monti) (Monti et al., 1997; Yang, 1993); tapered ileum implanted into a serous-lined extramural tunnel (Abol-Enein and Ghoneim, 1999); and the ileocecocystoplasty, which uses the ileocecal valve to provide continence (Sarosdy, 1992; Sutton et al., 1998) (Fig. 127.9). These channels are not free of complications, and long-term issues with catheterization, incontinence, and stomal stenosis can occur. A large retrospective study by Leslie et al. (2011) analyzed the long-term outcomes of 169 pediatric patients after either Mitrofanoff appendicovesicostomy or transverse ileal (Monti) tube. The authors report a 39% revision rate (8% stricture, 4% prolapse, 10% incontinence, 17% stomal stenosis at skin level). Despite revisions, 96% of channels were still functional at last follow-up. Most recently, in a cohort of 81 pediatric patients, Jacobsen et al. (2017) demonstrated that channel-associated complications cluster within the first 2 years postoperatively, followed by a significant decline. They also demonstrated a higher complication rate for ileal versus appendiceal channels. The choice of continent channel technique is often influenced by patient anatomy and surgeon preference.

Catheterization

Catheterization, in its many forms, is an effective method of bladder emptying and is a useful adjunct when efforts to increase intravesical pressure and/or decrease outlet resistance have been unsuccessful. Catheterization may also be a useful adjunct in patients who have filling/storage failure caused by bladder overactivity and/or sphincteric incontinence (Wein and Barrett, 1988). The common goals, irrespective of the mode of catheterization, are to provide low-pressure storage, preserve continence, avoid renal deterioration, minimize complications, and maintain quality of life.

Indwelling urethral catheters are generally used for short-term bladder drainage, and careful use of a small-bore catheter for a short time is unlikely to adversely affect the ultimate outcome, especially in initial bladder management after SCI (Lloyd et al., 1986). Long-term bladder drainage may be achieved by intermittent catheterization or by an indwelling suprapubic or urethral catheter. The most appropriate form of bladder drainage in patients requiring prolonged bladder management has long been debated. Most studies on catheterization have been retrospective and in patients with SCI, who represent the majority of patients requiring long-term catheterization. The main area of controversy concerns whether long-term indwelling catheterization in neurologically impaired patients is associated with an inferior outcome compared with CIC, specifically regarding urinary tract complications or quality of life.

Although CIC is currently the preferred management for patients requiring prolonged bladder drainage, it is a recent innovation. Intermittent catheterization was first introduced as a sterile procedure in 1949 by Guttman and, at the time, challenged the beliefs of most urologists (Guttman, 1949; Guttmann and Frankel, 1966). It was not until Lapides et al. (1972) introduced the concept of CIC that widespread usage became more common. **As the popularity of CIC grew, long-term indwelling catheterization was condemned, based on infectious risks and a perceived increased risk for other urologic complications.** Weld and Dmochowski (2000) reported a retrospective review of 316 patients with SCI with a mean follow-up of 18.3 years. Bladder management methods included chronic urethral catheterization in 114 patients, CIC in 92, spontaneous voiding in 74, and suprapubic catheterization in 36. Complications were classified as infectious complications (epididymitis and pyelonephritis), renal and bladder calculi, urethral complications (stricture and periurethral abscess), and radiographic abnormalities (vesicoureteral reflux and abnormal urographic findings). Overall, there were 398 complications identified, of which 236 developed in 61 patients (53.5%) on chronic urethral catheterization, 48 in 16 patients (44.4%) on suprapubic catheterization, 57 in 24 patients (32.4%) who voided spontaneously, and 57 in 25 patients (27.2%) on CIC. Separate bar graphs for each type of complication suggest the overall superiority of CIC as the least problematic long-term form of bladder management (Fig. 127.10).

FIG. 127.10 Complications related to specific bladder management methods: infectious (A); stone disease (B); urethral (C); radiographic abnormalities (D). (Modified from Weld KJ, Dmochowski RR: Effect of bladder management on urological complications in spinal cord injured patients. *J Urol* 163:768–772, 2000.)

The exact cause of upper tract deterioration in patients with long-term indwelling catheters is unclear because the bladder should be well drained by a catheter; however, it is likely related to chronic "occult" or subclinical DO in the face of sphincteric dyssynergy providing a functional obstruction. Regardless of the cause, it is clinically heralded by the development of poor detrusor compliance demonstrated on urodynamic studies. Jamil et al. (1999) reported on ambulatory urodynamics in 30 patients with SCI managed with an indwelling urethral catheter. They found that freely draining indwelling catheters did not guarantee consistently low intravesical pressure, observing intermittent detrusor contractions causing intravesical pressure greater than 40 cm H_2O in 11 patients (37%). Renal scarring was seen in 9 patients, 6 of whom demonstrated abnormal bladder contractions. **The authors concluded that suppression of high-pressure contractions in chronically catheterized patients may play a role in preventing renal deterioration.**

Periodic upper and lower tract evaluation using renal ultrasonography and cystoscopy should be considered in all patients who require prolonged bladder management. The use of urodynamics to monitor the bladder in neurologically impaired individuals is controversial**. At a minimum, we believe that urodynamics should be performed after the initial neurologic injury is stable and whenever any significant changes in continence or voiding function occur. The initial urodynamics is useful to direct early bladder management, while subsequent urodynamics evaluations are performed to determine if LUT changes, such as the development of dyssynergia, have occurred.**

Although bacteriuria is common in all forms of bladder catheterization, symptomatic infection is not. The presence of asymptomatic bacteriuria does not usually require treatment and should be distinguished from an invasive, symptomatic UTI. Treatment of asymptomatic bacteriuria has not proved beneficial, and the use of continuous prophylactic antibiotics is rarely indicated (Gribble and Puterman, 1993). Nevertheless, infectious complications are the most common complications associated with prolonged catheterization, and frequent catheter changes should be considered to reduce these complications (Weld and Dmochowski, 2000; Wyndaele, 2002). Much interest has recently been generated with catheter-associated infections in hospitalized patients. Under new rules by the Centers for Medicare and Medicaid Services, hospitals will not be compensated for catheter-associated UTIs, causing many hospitals to intensify their efforts in implementing preventive measures (Saint et al., 2009). For more information regarding bacteriuria and catheter-associated UTI, see Chapter 55.

Clean Intermittent Catheterization

CIC has proved to be the most effective and practical means of attaining a catheter-free state in the majority of patients who are unable to empty their bladders spontaneously. CIC is based on a theory proposed by Lapides that high intravesical pressure or bladder overdistention is primarily responsible for the development of UTI, not the bacteriuria. Theoretically, reduced blood flow to the bladder can lead to increased host susceptibility to bacterial invasion and UTI. Bacteria introduced by CIC would be neutralized by the host, and relatively sterile urine would be maintained as long as bladder distention and high intraluminal pressures were avoided. The long-term efficacy and safety of such a program has been demonstrated by Lapides and others (Weld and Dmochowski, 2000).

Whereas indwelling catheter drainage requires little input from the patient, **a cooperative, well-motivated patient or caregiver is a requirement for CIC.** The patient must have adequate hand control, or a family member must be willing to perform the catheterization. In addition, **there must be adequate urethral exposure.** In addition, proper selection of equipment for the patient's intelligence and financial level will increase patient acceptance of and compliance with a self-catheterization program. Successful CIC is intimately associated with patient compliance, and therefore patients should be monitored periodically to ensure catheterization is performed properly. **CIC should be used cautiously in patients known to have autonomic dysreflexia.**

Intermittent catheterization may be performed by clean, aseptic, or sterile techniques (Hudson and Murahata, 2005). CIC historically involved reusing a catheter several times before disposal. It is washed, generally with soap and water, and allowed to air-dry before storage. When reusing catheters, some have advocated boiling or microwaving for sterilization (Douglas et al., 1990). **In April 2008, in an attempt to decrease the incidence of UTIs in patients**

performing intermittent catheterization, Medicare policy regarding intermittent catheterization changed. Any patient requiring intermittent catheterization may obtain up to 200 sterile catheters per month for one-time use. This change in policy has negated the need for reusing catheters in most patients. **For adult patients, catheterization is typically performed at a minimum of every 4 to 6 hours to minimize bacterial dwell time. In most cases, catheterizations should be timed to maintain bladder volumes below the normal 400- to 500-mL capacity** to minimize bladder wall pressure. Even smaller volumes may be required if they have poor detrusor compliance. Pharmacologic therapy should be considered when urine leakage occurs between catheterization intervals or if high storage pressures develop.

Catheter choice is variable, but a 12- to l6-Fr soft catheter may be used for males and shorter catheters are available for females. Rigid catheters have the potential to injure the urethra in insensate males because they may not “make the bend” at the prostate, causing a false passage such that CIC may be difficult or impossible. In men, hydrophilic-coated catheters have been found to reduce the incidence of UTI and hematuria and have higher patient satisfaction rates than conventional plastic catheters (De Ridder et al., 2005; Vapnek et al., 2003). Larger catheters may be required in patients with augmentation cystoplasty who require bladder irrigation. Patients with recurrent UTIs, despite the use of single-use catheters, may obtain sterile catheter kits for sterile intermittent catheterization.

Continuous Catheterization

Long-term indwelling catheters should be considered when anatomic, functional, or caregiver limitations prohibit performance of intermittent catheterization. Continuous catheterization also may be indicated in patients with complications from persistent incontinence or autonomic dysreflexia or when a small bladder capacity prohibits effective CIC. Long-term catheterization may be accomplished by a urethral or suprapubic catheter. The basics of urethral catheterization, including the technique of suprapubic tube (SPT) insertion, are covered in Chapter 11.

In males, the benefits of an indwelling SPT over urethral catheterization include a lower incidence of epididymitis and urethral stricture disease (Weld and Dmochowski, 2000) and preserved sexual function (Rutkowski et al., 1995) (see Fig. 127.5). Furthermore, a meta-analysis by Han et al. (2017) demonstrated that bladder drainage with either suprapubic tube or intermittent catheterization was associated with a lower rate of UTI than transurethral catheterization when catheterization duration was longer than 5 days in the postoperative setting. Overall, suprapubic catheters have been associated with high rates of patient satisfaction. Barnes et al. (1993) concluded that long-term suprapubic catheters were well tolerated by patients with neuropathic bladders. Of 32 patients, 84% were satisfied; however, follow-up was short (mean 23 months), and in 2 of 12 patients assessable at more than 2 years, creatinine levels increased. Other problems included recurrent catheter blockage in 38%, recurrent symptomatic urinary infections in 23%, and displaced catheters requiring reinsertion in the operating room in 15%. Urethral leakage occurred in 8 of 14 females with a suprapubic catheter alone and in 6 of 16 males. Patients using a suprapubic catheter should be advised that urinary incontinence may commence or worsen in the setting of sphincteric incontinence or reflex DO, because active opening of the sphincteric unit will occur in the absence of dyssynergia.

A controversial issue, common to all long-term indwelling catheters, is the development of bladder cancer. **The long-term risk of carcinoma in the patient with SCI with a chronic catheter has been estimated to be 8% to 10%** (Delnay et al., 1999; Locke et al., 1985). Kaufman et al. (1977) were among the first to recognize that patients with SCI and chronic indwelling catheters had an increased incidence of bladder cancer, particularly squamous cell carcinoma (SCC). Several others reported similar findings (Chao et al., 1993; Stonehill et al., 1996). Since then, the association between chronic indwelling catheterization and the development of bladder carcinoma has been debated. **No associations with intermittent catheterization have been identified.** Chronic inflammation is the most likely causative factor and may be caused by the indwelling catheter, bladder calculi, and/or recurrent infections. It is not clear whether earlier treatment of these conditions or better follow-up will lessen the risk for bladder carcinoma. A mechanism for the development of bladder carcinoma secondary to long-term inflammation was described by Wall et al. (2001). **According to their report, inducible nitric oxide synthase expressed by inflammatory macrophages in areas of chronic inflammation may lead to the formation of potentially carcinogenic nitrosamines in the bladder.** For more on the development of carcinoma related to chronic catheterization, see Chapter 135.

When SCC is identified in patients with SCI, it is often advanced and commonly fatal; however, routine screening cystoscopy for at-risk patients with SCI is controversial. **Although some authors suggest that screening**

cystoscopy conveys a survival advantage by identifying bladder cancer at an earlier stage (Navon et al., 1997)**, others have found no advantage for screening** (Hamid et al., 2003; Yang and Clowers, 1999). Cytologic examination, although commonly performed, is not useful for detecting SCC (Bejany et al., 1987). In addition, SCC may not always be cystoscopically detectable (Kaufman et al., 1977). For this reason, routine random biopsies have been advocated by some (Stonehill et al., 1996). **Despite the lack of data in patients without SCI, most urologists recommend all patients with chronic catheters undergo annual screening, generally starting after 8 years** (Stonehill et al., 1996)**. Gross hematuria has been reported as the most common manifesting symptom in patients eventually diagnosed with bladder cancer** (Hess et al., 2003). Despite disparate opinions regarding screening, certainly all would agree that patients with new-onset gross hematuria should be evaluated with upper tract imaging, urine cytology, cystoscopy, and perhaps random biopsies. **Other patients to consider for close surveillance include those known risk factors for the development of carcinoma, such as recurrent UTIs or bladder stones.**

Increasing Intravesical Pressure or Facilitating Bladder Contractility

External Compression (Credé) and Valsalva Maneuver

The Credé maneuver (manual compression of the bladder) is most effective in patients with decreased bladder tone who can generate an intravesical pressure greater than 50 cm H_2O and have decreased bladder outlet resistance (Wein and Barrett, 1988). The open-handed Credé method involves placement of the thumbs of each hand over the anterior superior iliac spines and the digits over the suprapubic area, and downward compression on the fundus of the bladder with the fingertips. For some patients, this maneuver can be accomplished more efficiently by using a closed fist or a rolled-up towel. Straining as the Credé maneuver is applied is generally counterproductive because this increases intra-abdominal pressure and causes bulging of the abdominal wall, which then lifts the compressing hands off the fundus of the bladder. If the guarding reflex arc is intact, this also may produce a striated sphincter contraction. The Credé maneuver is much easier in a patient with a lax, lean abdominal wall than in one with a taut or obese one, and it is more readily performed in a child than an adult.

A similar increase in intravesical pressure may be achieved by abdominal straining (Valsalva maneuver). The proper technique involves sitting and letting the abdomen protrude forward on the thighs. During straining in this position, hugging of the knees and legs may be advantageous to prevent any bulging of the abdomen. To increase intravesical pressure in this manner requires voluntary control of the abdominal wall and diaphragmatic muscles.

"Voiding" by the Credé or Valsalva maneuver is generally discouraged, because it is nonphysiologic and is resisted by the same forces that normally resist stress incontinence. In many cases, an increase in outlet resistance may occur reflexively with external compression maneuvers. If adequate emptying does not occur in the properly selected patient, other types of therapy to decrease outlet resistance may be considered; however, these treatments may adversely affect urinary continence.

The best chance for success with this mode of therapy is in the patient with an areflexic bladder and some degree of outlet denervation. This is most commonly seen in the patient with an autonomous neurogenic bladder (Lapides classification), T11 through L2 SCI in whom the sympathetic nervous supply is damaged, or after outlet resistance is decreased surgically or by botulinum toxin injection. Most of these patients already have stress incontinence, and the Credé or Valsalva maneuver simply helps the patient overcome outlet resistance to empty the bladder at a convenient time. These techniques also may be useful to decompress a neobladder when the outlet resistance is low either by volitional sphincteric relaxation or when surgically induced.

Vesicoureteral reflux is a relative contraindication to external compression or the Valsalva maneuver, especially in patients capable of generating a high intravesical pressure. The most flagrant misuse of this form of management is in the patient with a neurogenic bladder and poor detrusor compliance, because the increased storage pressures can cause upper tract deterioration with minimal filling. External compression or Valsalva maneuvers will only further aggravate this already dangerous situation.

Even when the patient has a flaccid bladder and/or low detrusor leak point pressures, close follow-up and periodic evaluation are necessary to avoid upper tract deterioration. Chang et al. (2000) reported the long-term urologic complications and residual volumes of 74 SCI patients with flaccid bladders who routinely performed the Credé maneuver as their primary form of bladder management for more than 20 years. Residual urine volume was greater than 100 mL in 93% of patients, and 50% were greater than 300 mL. The authors also reported that 59.5% developed ureteral dilation, 35.1% developed hydronephrosis, and 16.2% suffered renal deterioration. Males were significantly more likely to develop these complications than females, probably because of increased outlet resistance. Other complications included recurrent UTIs, pyuria, urolithiasis, epididymo-orchitis, genital-rectal prolapse, and hemorrhoids (Chang et al., 2000; Wyndaele, 2008).

Promotion or Initiation of Reflex Contractions

In patients with SCI and an intact sacral spinal cord, voiding can be elicited by exploiting existing spinal reflexes. The sacral micturition reflex occurs when tension receptors within the bladder wall are stimulated by bladder filling and activate sensory afferent neurons. Motor efferents from the spinal cord respond by generating a reflexive bladder contraction and, when of adequate magnitude, will result in voiding. Bladder contractions obtained in this manner are often involuntary and sporadic. In some cases, patients with SCI may be able to trigger this reflex voluntarily by manual stimulation of areas within the sacral or lumbar dermatomes. **According to the classic reference by Glahn** (1974)**, the most effective method of initiating a reflex contraction is rhythmic suprapubic manual pressure (seven or eight pushes every 3 seconds). Quick repetitive stimulation in this manner is thought to produce a summation effect on the tension receptors in the bladder wall, resulting in activation of the bladder reflex arc. Other commonly used maneuvers to induce reflex detrusor contraction include pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; or digital rectal stimulation** (Wein and Barrett, 1988). Patients able to void in such a way are encouraged to find their own optimal trigger points and position for urination. Reflex voiding depends on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or conditions characterized by DO. Surgical procedures to reduce outlet resistance should be considered if significant obstruction or sphincter dyssynergia are present. Complications with this voiding technique are most often related to the use of external collection devices or from the development of high-pressure storage resulting in upper tract deterioration. To ensure compliance, periodic surveillance should be performed with regular urodynamic evaluation.

Intraurethral Valve-Pump for Women With Impaired

Detrusor Contractility

The inFlow intraurethral valve-pump was FDA approved in 2014 for use in adult females with incomplete bladder emptying resulting from impaired detrusor contractility (IDC). It is a silicone device containing a miniature internal pump available in lengths ranging from 3 to 7 cm and diameter of 24 or 28 Fr. Initial sizing and placement is performed by the physician and must be changed every 29 days. Subsequent insertions may be performed by the patient or caregiver. The device is inserted into the urethra using a disposable introducer and fixed in place by silicone fins at the level of the bladder neck and a flexible flange at the urethral meatus. To void, the patient places a remote control (inFlow activator) over the suprapubic area and presses a button, which magnetically activates an internal pump to generate a urine flow of 10 to 12 mL/s. When the button is released, the valve closes to restore continence.

In a multi-center single-arm crossover study, use of inFlow resulted in significant improvements in quality-of-life scores compared with baseline CIC in the 77 patients who completed the 16-week inFlow treatment phase (Chen et al., 2005). Postvoid residual was comparable during baseline CIC and inFlow treatment phases (20.3 cc vs. 16.1 cc, respectively). However, there was a large early withdrawal rate of 61.9% (169/273), mainly resulting from initial discomfort and leakage. In a cohort of 92 patients with long-term (1 year) follow-up, Madjar et al. (2000) also reported a high dropout rate (77.1% overall) but a 100% satisfaction rate in the 21 patients who were still using the device at 1 year. Adverse events included device migration into the bladder ($n = 4$), asymptomatic bacteriuria ($n = 15$), and symptomatic UTIs ($n = 4$). With a protocol of pre-insertion patient education and post-insertion nursing support, a higher rate of device acceptance may be achieved (Lynch et al., 2003).

Stimulated Myoplasty for Bladder Emptying

Few treatment options are available for patients with detrusor underactivity except for self-intermittent catheterization. Restoration of bladder contractility remains an elusive goal for most patients with this condition. The first animal feasibility studies to augment bladder contractility used a unilateral rectus abdominis muscle wrap over the bladder to facilitate bladder emptying (Chancellor et al., 1994a). The rectus muscle, with intact neurovascular pedicle, was dissected free at one end and wrapped over the bladder to create a spherical configuration housing the bladder. Evaluation of the transposed muscle showed no damage to the blood supply or innervation of the rectus muscle, and the underlying bladder retained its volume despite neurogenically induced underactivity. This model was touted as the precursor for a clinical trial in which the patient would learn to contract his rectus muscle voluntarily and create sufficient extrinsic pressure to void. The first case report of rectus myoplasty involved a 33-year-old man with an L4 SCI from a gunshot wound 10 years before enterocystoplasty covered by the left rectus muscle transposed over the bladder (Chancellor et al., 1994b). One month later, the patient could void by contracting his rectus muscle, generating 50 cm H_2O detrusor pressure. This ability persisted for 11 months until the case was reported in the literature. Use of rectus muscle for myoplasty in humans was not reported again for 23 years. In a case series of 5 patients with acontractile bladder resulting from SCI, complete spontaneous voiding was achieved in all patients after rectus abdominus detrusor myoplasty (Agarwal et al., 2017). At 6 months, the authors demonstrated a statistically significant decrease in postvoid residual and statistically significant increases in urine flow rate, bladder contractility, and detrusor pressure.

Latissimus dorsi has also been used for myoplasty. Von Heyden et al. (1998) studied free latissimus dorsi muscle flaps for bladder myoplasty in dogs; revascularization and electrical stimulation of the thoracodorsal nerve successfully induced pressures sufficient for partial evacuation of the bladder. The advantage of a singular nerve supply with ample geometry provided by the latissimus dorsi free flap led to the first clinical application in 1998 by Stenzl et al. (1998). Three patients with bladder acontractility were treated with latissimus dorsi myoplasty, and all three were able to void by abdominal straining. In a larger clinical study using the free transfer of the latissimus dorsi muscle to restore voluntary voiding, 14 of 20 patients were able to void spontaneously with postvoid residual volumes of less than 100 mL (Ninkovic et al., 2003). **The largest latissimus dorsi detrusor myoplasty experience was reported by Gakis et al.** (2011) **in 24 patients with detrusor underactivity requiring CIC and a mean follow-up of 46 months. Latissimus dorsi detrusor myoplasty resulted in complete voluntary voiding in 71% of patients with a 91% reduction in UTIs. Three patients reduced the frequency of catheterization by 50%, and 4 patients had no improvement.**

Key Points: Additional Therapies for Emptying

- Indications for catheterizable channel include difficulty catheterizing per urethra, urethral scarring, and urethral incompetence requiring outlet closure.
- Complications of continent catheterizable channels include long-term issues with catheterization, incontinence, and stomal stenosis.
- Asymptomatic bacteriuria is common in catheterized patients and does not require treatment unless the patient becomes symptomatic.
- Chronic catheterization (CIC or indwelling) may lead to poor bladder compliance and upper tract deterioration; thus periodic surveillance is recommended.
- Credé and Valsalva maneuvers may elevate intravesical pressure enough to cause upper tract deterioration, especially in setting of poor detrusor compliance.
- Reflex voiding depends on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or neurogenic DO.

Additional Therapies for Storage and Emptying Failure: Circumventing the Problem

Patients with urinary incontinence may choose to wear an external collecting device or absorbent pad to manage leakage. For some, their incontinence is minimal, or they are unwilling or unable to undergo more definitive treatment. However, in some instances, patients have failed multiple anti-incontinence procedures and external collecting devices or pads are the only management options available.

External Collecting Devices

No external urinary collecting device for females has been successful or effective. The female urethral meatal anatomy has made it difficult to design a leak-proof apparatus that is easy to apply and maintain. **However, external collecting devices for men—the condom catheter, penile sheath, or Texas catheter—are generally effective in urine collection. For male patients who are unable to perform CIC because of cognitive impairment, quadriplegia, or lack of reliable assistance from a caregiver, the condom catheter may be preferable over an indwelling urethral catheter.** A study by Saint et al. (2006) reported the results of a randomized controlled trial of 75 hospitalized male veterans in which 41 men were managed with indwelling urethral catheter and 34 men with condom catheter. The median hospital stay was 3 days. **Condom catheters were associated with a lower incidence of bacteriuria, symptomatic UTIs, and death compared with the use of an indwelling urethral catheter. Patients also reported that external urinary collection devices were more comfortable and less restrictive on daily activities than indwelling catheters.** Despite the reduced incidence of adverse outcomes, the use of external collection devices and absorbent products is associated with a higher risk for UTIs compared with cases in which no appliances are used (Sturmann and O'Grady, 1989). It is generally recommended that condom catheters be changed daily because the risk for UTI is increased when catheters are changed less frequently (Waites et al., 1993; Zimakoff et al., 1996). **The use of a condom catheter is not free of complications. It can cause allergic**

reactions, skin maceration, and/or penile edema. Furthermore, the penile skin and glans should be examined at every catheter change to ensure no skin breakdown or contact reactions have occurred (Newman, 1999). These devices have the potential to cause pressure necrosis of the penis and, when severe, may even damage the urethra (Golji, 1981). **Pressure-related complications are more likely to occur in patients with impaired sensation, such as those with neurogenic LUT dysfunction** (Golji, 1981). External urine collecting devices also are prone to dislodge or fall off, especially if the patient is wearing an inappropriate size. In addition, patients with SCI may have reflex penile retraction and paralysis associated with pelvic bending, making it difficult to maintain the device. Van Arsdalen et al. (1981) reported on the use of a malleable penile prosthesis in this type of patient to facilitate applying and maintaining a condom catheter. Zermann et al. (2006) describe the long-term results of penile prosthetic surgery for urinary incontinence and/or erectile dysfunction in neurologically impaired patients. At a mean follow-up of 7.2 years, 90.3% of urinary management problems were resolved. The overall infection rate was 5%, and the rate of explantation was 7.7%, which is comparable with the explantation rate in non-neurogenic patients.

Absorbent Products

Urinary incontinence can be a socially debilitating problem leading to fear of odor, discovery, and embarrassment. Many patients with urinary incontinence wear some type of absorbent product, which may include pads, shields, drip collectors, guards, undergarments, briefs, diapers, or underpads. **Consumers spend billions of dollars on these products** (Erekson et al., 2008; Getliffe et al., 2007) **and for the majority, selection is often based on trial and error, cost, convenience, and manufacturers' claims** (Baker and Norton, 1996; Fantl et al., 1996). Recently, the National Association for Continence (NAFC) formed a council of experts with the goal of establishing national, independent quality performance standards for disposable adult absorbent products. The full recommendations of the NAFC Council include nine performance assessment parameters: "rewet rate (product's ability to withstand multiple incontinent episodes between changes), rate of acquisition (the speed at which urine is drawn away from the skin by a product), product retention capacity (product's capacity to hold fluid without rewetting the skin), sizing options, absorbency levels, product safety, closure technology, breathable zones (air permeability across a textile-like fabric at a controlled differential pressure), and elasticity” (Muller and McInnis, 2013). More research is needed to evaluate the impact of these parameters on cost and quality of care.

Often recognized as the authority in the management of the incontinent patient, urologists should acknowledge the basic nursing principles and skin care recommendations that may significantly contribute to patient care. Absorbent products should be changed frequently to help avoid buildup of odor and limit exposure of the skin to urine. Prolonged exposure of the skin to a wet environment may lead to supersaturation and disruption of the skin's protective barriers, promoting skin maceration, dermatitis, and possibly infection. **Incontinence-associated dermatitis (IAD) can be defined as inflammation of the surface of the skin with redness, edema, and, in some cases, bullae containing clear exudate** (Gray et al., 2007)**. IAD predominately occurs in skin folds and may promote candidiasis or bacterial skin infections.** Gray et al. (2007) published an excellent review of the epidemiology, pathophysiology, and management of IAD with recommendations for prevention and treatment.

Further information regarding the types of absorbent products available for males and females, including a review of skin care management, external collection, and urethral compression devices can be found in the book by Newman and Wein (2009) and the comprehensive resource guide available from the NAFC (2008) (http://www.nafc.org).

Key Points: Circumventing the Problem

- Condom catheter use is associated with lower rate of bacteriuria, symptomatic UTIs, and death than indwelling Foley; it is also more comfortable and less restrictive.
- Complications of condom catheter include allergic reactions, penile edema, and higher risk for pressure sores in patients with impaired sensation or cognition.
- Consumers spend billions of dollars on absorbent products; selection is often based on trial and error, cost, convenience, and manufacturers’ claims.
- IAD is inflammation of skin with redness, edema, and/or bullae with clear exudate; it is often in skin folds and may promote candidiasis or bacterial

skin infections.

Summary

Disorders of the storage and emptying phases of micturition have various causes and can be classified by the location of the dysfunction, either at the bladder level or the bladder outlet. Treatment strategies are numerous and often combine medical and surgical management. Continued research is warranted to further our understanding of the pathophysiology of storage and emptying failure so that we may continue to improve patients’ quality of life.

Aging and Geriatric Urology

Tomas L. Griebling MD, MPH

Aging is a universal process that affects all living organisms. Alterations in anatomy and physiology associated with the normal aging process lead to functional changes in all aspects of human medicine including the genitourinary system. This chapter focuses on human aging and the associated alterations in structure and function that affect urologic care for older adults.

Dr. Ignatz Leo Nacher was the first to use *geriatrics* as a clinical term in a scientific publication in 1909 (Nacher, 1909). That article highlighted early concepts about considering care for older adults as a distinct branch of medicine. More than a century later, geriatrics is a recognized and respected distinct specialty not only within general medicine but also in multiple other health care disciplines, including nursing, pharmacy, physical and occupational therapy, social work, and others. More recently, the growing need for geriatrics expertise in all of the medical and surgical specialties including urology has been recognized (Bell et al., 2011; Drach and Griebling, 2003). Research efforts and educational materials have been developed that have helped to expand knowledge about the unique aspects of medical needs and care delivery for older adults with urologic health problems (Griebling 2009a, 2009b, 2014a; Guzzo et al., 2013; Reuben et al., 2014; Webb and Duthie, 2008).

In clinical medicine, the term ***geriatrics* is most commonly used to refer to care of patients 65 year of age or older.** In part, this is a social construct because this is the age when Medicare and Social Security benefits have traditionally started for people in the United States. The World Health Organization (WHO) actually classifies people over the age of 60 as being “elderly,” because life expectancy is still shorter in many parts of the developing world. With continuing advances in medical care, and extended longevity in many developed countries, many would argue that clinical geriatrics now encompasses an even older population, often focused on those 70 years and older. However, in many circumstances, **chronologic age may be a much less**

important factor compared with physiologic or functional age.

One of the basic principles in geriatric medicine is a focus on patient-centered care. This places the goals of care for patients, their caregivers, and other loved ones at the core of clinical evaluation and treatment. In some cases the goal may be treatment with curative intent. However, in many instances this may not be possible. In all cases, there should be an **emphasis on quality of life and stabilization or improvement in functional status.** This frequently includes a goal to maintain independence as long as possible and to reduce the need for assistance or care from others to the extent possible. Promotion of urinary continence and improved bladder function is a good example of this type of care within the scope of urologic practice. Improvement in independent toileting and continence status can reduce the need for caregiver assistance and may in turn decrease the risk of need for nursing home placement (Andel et al., 2007).

Biology and Principles of Aging

There are several plausible theories about why people age and experience changes over time. The **Hayflick "limit"** describes the phenomenon of limitations in the number of cellular replication cycles inherent to most cell types (Hayflick and Moorhead, 1961). This may be due to a variety of factors. **Telomere shortening** has been identified as a common cellular change seen with aging. **Activation of various tumor suppressor genes** or other genetic pathways may also either promote or suppress cellular senescence. **Release of free radicals and other types of oxidative stress increase with aging** and can lead to mitochondrial damage and other intracellular changes. Some cell types exhibit **apoptosis or programmed cell death.** Numerous inflammatory biomarkers have been shown to increase with age and could potentially accelerate the aging process. These **accumulated changes can lead to the alterations in tissue and organ function commonly seen with advancing age.** These types of changes can influence clinical outcomes, including tissue and wound healing, restoration of function, and outcomes of reconstructive urologic surgical procedures (Griebling, 2009a).

Physiologic Aging

Changes in function with increasing age can be seen in essentially all organ systems. Generalized changes can be exacerbated by specific disease progression. A number of these different processes have direct impact on genitourinary health, urologic function, and clinical decision making relative to urologic care.

Renal blood flow decreases with aging. This can be caused by atherosclerotic plaque formation in the renal arteries and other vascular diseases. Kidney mass also decreases progressively after 65 years of age. This leads to a **concomitant decrease in the glomerular filtration rate of approximately 10 mL/min per decade,** reaching about 50% by age 80. Approximately 26% of all adults over the age of 70 have some degree of chronic renal impairment. **This can have substantial impact on dosing of medications cleared by renal metabolism** (Hanlon et al., 2009). In many cases, lower doses will be adequate to achieve clinical effects, and doses typically used in younger patients may lead to toxicity or untoward side effects. Renal concentrating ability is also reduced, and older adults tend to make a larger volume of more dilute urine (Sands, 2003).

Accurate estimation of renal function in older adults can be challenging. **Serum creatinine levels alone may not reflect actual renal function,** particularly in frail older adults or those with reduced lean body mass. In these cases, serum creatinine measurements will tend to overestimate function, and underestimate the degree of renal impairment (Giannelli et al., 2007). Measures that calculate estimated glomerular filtration rates, including the Cockcraft-Gault equation, will tend to be more accurate in this elderly population (Scrutinio et al., 2009). Routine assessment and reporting of estimated GFR can help to improve prescribing accuracy for drugs that require renal metabolism (Kurtal et al., 2009).

The diurnal pattern of water consumption and urine production also changes with aging. Total water intake appears to decrease among older adults with aging, with population studies indicating only 19% to 27% of geriatric patients actually reach the daily recommended levels of fluid consumption (Zizza et al., 2009). Endogenous secretion of arginine vasopressin decreases with age. Because of this, older adults tend to excrete the majority of their fluid output at night, which can lead to symptomatic nocturia (Tani et al., 2008). This relative nocturnal polyuria can be a major contributing factor to clinically bothersome symptoms (Natsume et al., 2009).

Cardiac compliance and elasticity decrease with aging, which leads to decreased cardiac output and stroke volume. This can have important implications, particularly when considering older adults as candidates for urologic surgery. Hypertension is also a common condition seen with aging, which can negatively influence functional reserve capacity. Hypertension in older adults can be caused by a myriad of factors, including renovascular and other causes.

The **respiratory system** undergoes substantial changes with aging. Pulmonary surface area for oxygen diffusion decreases leading to changes in ventilation and perfusion ratio. Chest wall elasticity and respiratory muscle strength both decrease, and there is decreased maximal expansion. Pulmonary fibrosis and chronic obstructive pulmonary disease are common conditions seen with aging that can also negatively influence respiratory function. Cigarette smoking increases these risks and exacerbates age-related changes. Increased cough may worsen symptoms among patients with concomitant stress urinary incontinence. As with cardiovascular disease, alterations in pulmonary function play a major role in consideration for surgical therapy in older adults. **Although the majority of deaths in the perioperative period in geriatric patients are due to cardiovascular events** such as myocardial infarction and stroke, **the majority of prolonged hospitalizations are due to pulmonary problems** such as pulmonary embolism, pneumonia, and respiratory failure and difficulty weaning from ventilator support (Somme et al., 2003).

Hepatic function also declines with time. Loss of hepatocytes leads to **decreased metabolic efficiency for drugs cleared by hepatic metabolism.** Alterations in the cytochrome P450 mechanism are common and can be influenced by a variety of medications. This can alter hepatic metabolism and may require dose adjustment of medications cleared by the liver. It is also important to consider drug-drug interactions that may be influenced by changes in the cytochrome P450 pathway. Certain foods, particularly grapefruit, can also interfere with the cytochrome P450 pathway and potentially impair drug metabolism.

Immunologic function, particularly T-cell mediated immunity, tends to slowly decline with age. This leads to a generalized increase in the risk of infections among older adults including a greater risk for upper and lower urinary tract infections (UTIs) and pneumonia.

Gastroenterologic changes include a generalized slowing of bowel motility, which can lead to alterations in stool frequency and consistency. **Altered water reabsorption from the colon can increase risk for constipation.** This can be particularly affected by anticholinergic and other medications, which may slow bowel motility. This in turn increases the risk for constipation and fecal impaction with aging. These conditions can be exacerbated by medications used in the treatment of some urologic conditions such as antimuscarinics prescribed for overactive bladder, urinary urgency and frequency, and urgency UI (Kim et al., 2014).

Vascular changes are common with aging. These include changes in peripheral vasculature, cardiac and central nervous system vascular anatomy, and renal perfusion. Hypertension, tobacco use, and diabetes contribute to vascular disorders seen more commonly with aging. Plaque formation and atherosclerotic disease may limit circulation to the kidneys, bladder, penis, and other genitourinary organs. Decreased penile blood flow can lead to erectile dysfunction in elderly men (Justo et al., 2010). Pelvic ischemia has also been linked to the subsequent development of lower urinary tract symptoms (LUTS) in older adults (Kim et al., 2010; Pinggera et al., 2008). Color Doppler ultrasound demonstrates diminished arterial blood flow is associated with pelvic ischemia and higher rates of lower urinary tract symptoms. Animal models show that pelvic ischemia is associated with increased levels of proinflammatory cytokines and other biomarkers suggesting that oxidative stress plays a role in this process (Nomiya et al., 2012). Free radical release and oxidative stress may cause ultrastructural damage that can lead to neurodegeneration and other anatomic and functional abnormalities (Azadzoi et al., 2007, 2010, 2011; Tyagi et al., 2014b). Early research suggests that melatonin and other compounds such as free radical scavengers could be potential agents to prevent urologic sequelae from this type of ischemia (Nomiya et al., 2013).

Metabolic changes are common with aging. Rates of the metabolic syndrome and type II diabetes mellitus increase substantially with advancing age. These conditions can contribute to multiple clinical conditions, including vascular insufficiency, erectile dysfunction, renal impairment, and bladder dysfunction (Park et al., 2008). With aging, there is a **relative increase in adipose tissue and a loss of lean body mass and muscle.** This influences fluid distribution and drug metabolism and increases the rate of accumulation of lipophilic metabolites. **Because of this, many lipophilic drugs must be dose titrated in older adults.** Obesity and overweight have reached epidemic proportions in the United States, and this is associated with increased rates of associated medical conditions, including diabetes and metabolic syndrome.

Aging and the Lower Urinary System

Many of the common genitourinary conditions occur with higher incidence and prevalence rates in older adults, but these should not necessarily be considered a normal or inevitable part of the aging process. Examples include UTIs, urinary incontinence, erectile and sexual dysfunction, and many urologic malignancies. Various changes commonly occur in the genitourinary tract as a result of the normal aging process. **One of the greatest challenges in geriatric urology is to differentiate between normal aging and pathologic processes** that can affect the genitourinary system and lead to associated symptoms.

Several structural changes that occur in the bladder with aging have been linked to functional changes that can cause specific clinical symptoms (DuBeau, 2006). The ratio of smooth muscle to collagen in the wall of the bladder decreases, which may lead to decreased contractile strength. Studies using electron microscopy and other structural imaging modalities have demonstrated these changes as well as development of dense bands and loss of caveolae (Elbadawi et al., 1993; Lowalekar et al., 2012). These alterations have been linked to increased involuntary detrusor contractions and changes in contraction strength and velocity. Functional bladder innervation also appears to diminish over time with chronic obstruction or overactivity (Fry et al., 2011). Changes in detrusor anatomy can also lead to a decrease in elasticity and compliance, defined as the change in bladder volume related to bladder pressure. These alterations can lead to changes in urine storage and bladder emptying (Elbadawi et al., 1997). Sensory changes may be caused by alterations in the epithelium and associated receptors and neurotransmitters. Oxidative stress damage may also occur as a result of the aging process and may be associated with symptomatic bladder dysfunction (Aybek et al., 2011). Bladder capacity tends to remain relatively stable or decrease only slightly with advancing age (Pfisterer et al., 2006a, 2006b).

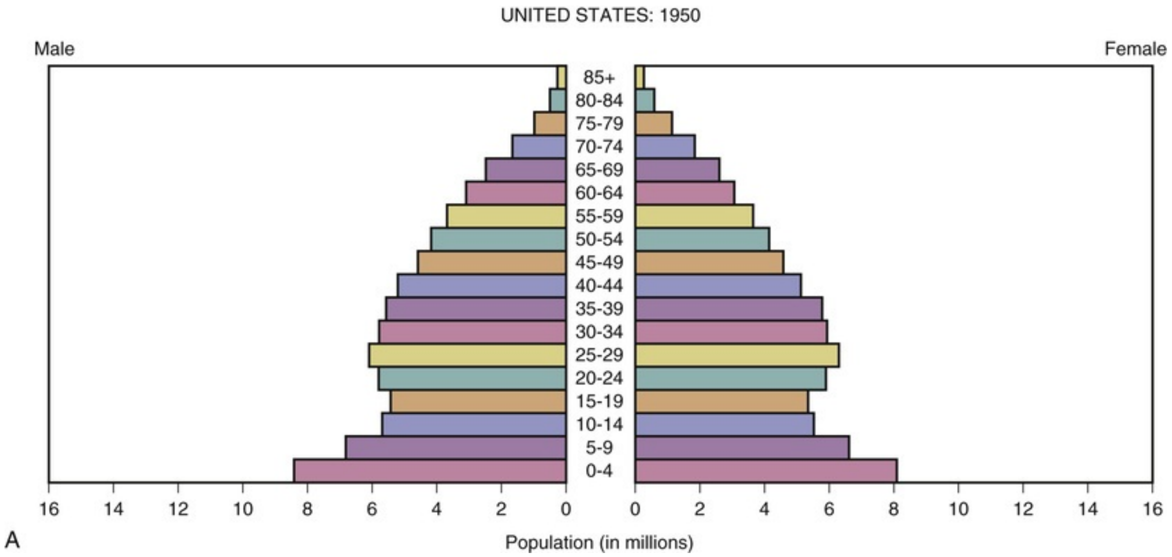
Progressive anatomic changes in pelvic floor support and muscle strength can also occur with aging. Cadaveric studies using biopsies of the urogenital diaphragm have documented that striated muscle tissue is substantially reduced or absent in many older women relative to connective tissue (Betschart et al., 2008). However, aging may not be the sole risk factor, and other variables including parity and history of vaginal delivery should be considered (Weemhoff et al., 2010). Bony structural support in the pelvis may also contribute to these changes and can potentially be influenced by geriatric skeletal disorders such as osteopenia or osteoporosis (Richter et al., 2013). **Pelvic floor muscle dysfunction is common among elderly women,** and research indicates many of them may not be able to generate voluntary muscle contractions on initial examination (Talasz et al., 2012). Some of this observed change in pelvic floor support may be due to apoptotic cellular changes in these tissues (Saatli et al., 2014).

Decreased striated muscle density in the rhabdosphincter can lead to an increased propensity for stress urinary incontinence, particularly in elderly women. These anatomic changes may be caused, at least in part, by apoptosis associated with aging (Strasser et al., 1999, 2000). This can subsequently lead to a loss of the normal circumferential anatomy and appropriate urethral resistance and closure pressures (Klauser et al., 2004; Kurihara et al., 2004).

Demographics of Aging

Aging and Population Trends

The overall population of the United States, and many other developed countries, is aging at a very rapid pace. This is due to a number of factors, including improved longevity, decreased overall birth rates, and enhanced medical technology that makes effective treatment for many conditions possible. Older adults, defined as those 65 years of age and older, currently account for approximately 13% of the total US population. However, it is estimated that this will increase to at least 20% by the year 2030 (Fig. 128.1). **Those over the age of 85 represent the fastest-growing segment of the United States population.** The aging of the “Baby Boom” generation, including those born between 1946 and 1964, is also contributing to this demographic trend. Approximately 10,000 people per day now turn 65 years of age in the United States. This is a global phenomenon and is occurring in almost all portions of the world with the exception of sub-Saharan Africa, where mean life expectancy is still relatively shorter. Worldwide, approximately 420 million people were over the age of 65 in 2000, and it is estimated that this will increase to more than 973 million by 2030 (Centers for Disease Control and Prevention, 2014). Remaining life expectancy for those already aged 65 continues to steadily increase in the United States and many developed countries worldwide.



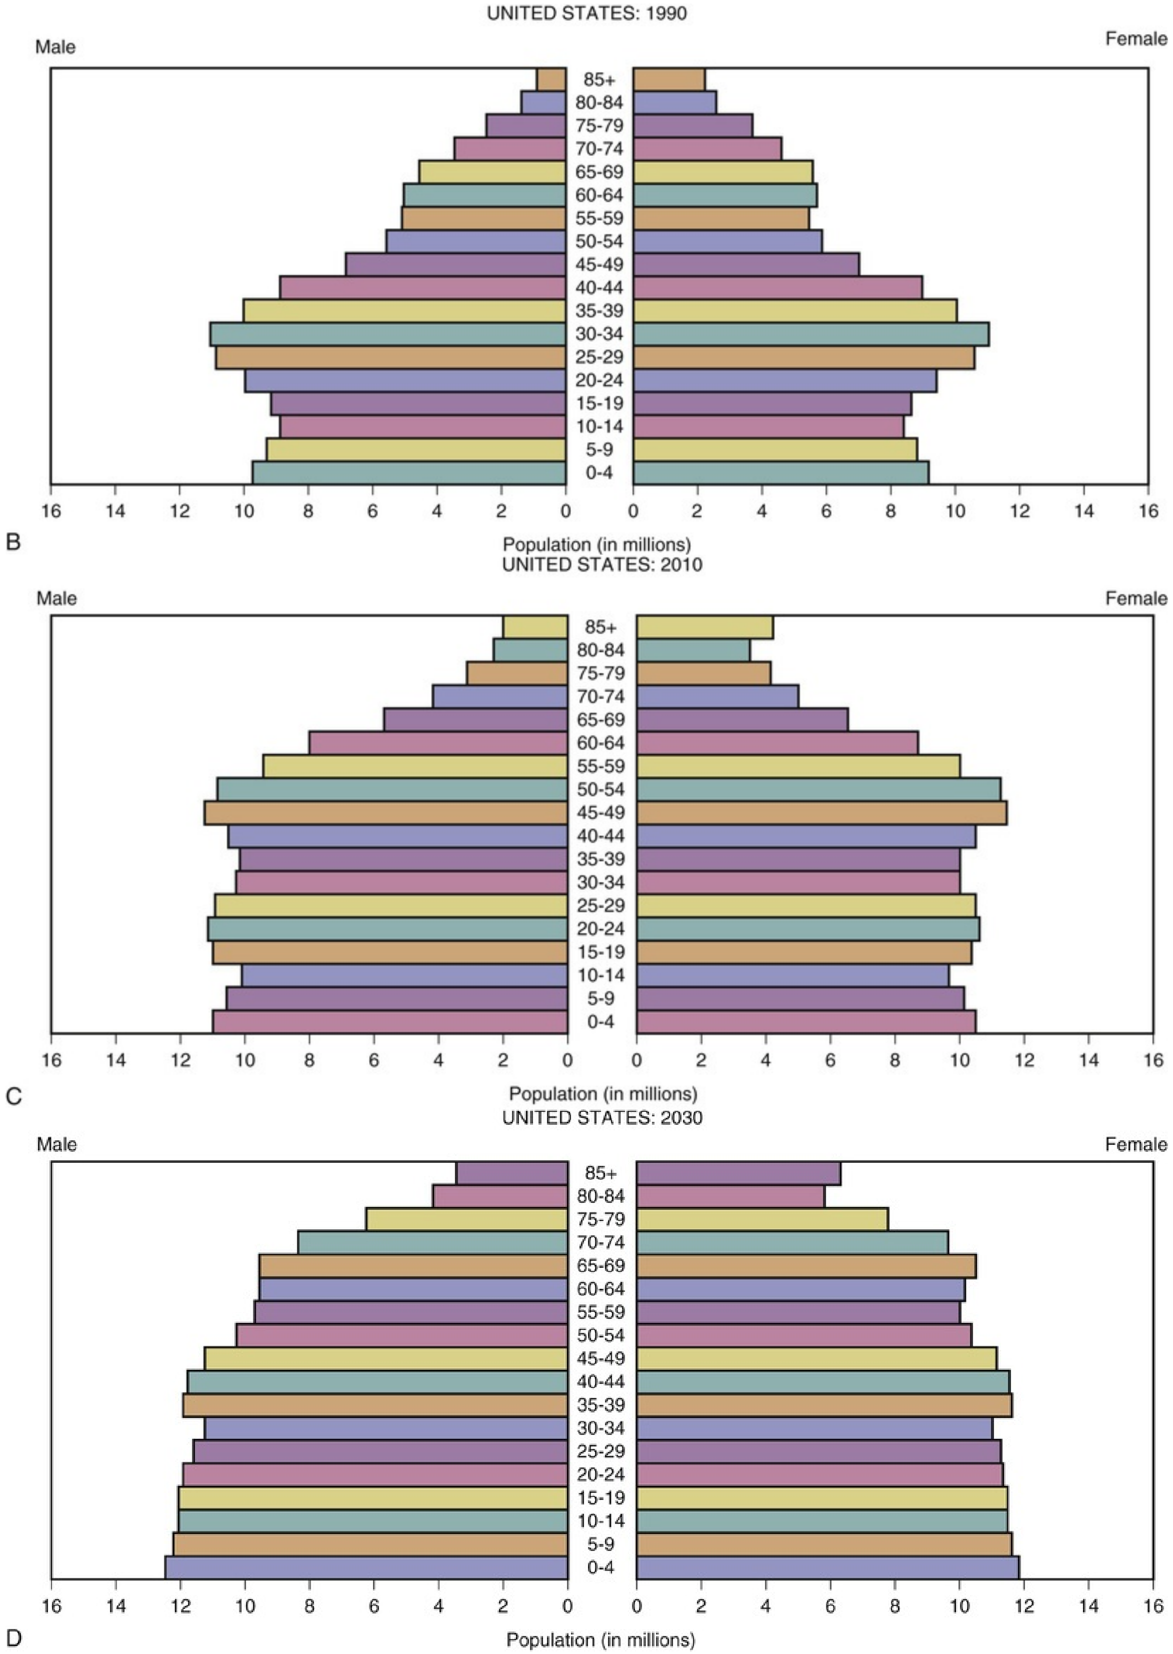


FIG. 128.1 Age-sex population pyramids based on United States Census data. (A) 1950 census. (B) 1990 census. (C) 2010 census. (D) 2030

(projected). Note the sizeable increase in total population and the progressive change over time from a pyramid shape, where the majority of the total population is relatively young, to a rectangular shape, where a substantially larger portion of the population is more than 65 years of age. The pronounced bulge in the graphs for 1990 and 2010 represents the "Baby Boom" generation. (Source: United States Census Bureau, https://www.census.gov).

The majority of older adults continue to live in the community, with only a minority requiring residential long-term care in nursing home or other types of facilities. The need for nursing home services does increase with advancing age, with approximately 15% of those over 85 years of age living in long-term care facilities (Federal Interagency Forum on Aging-Related Statistics, 2012).

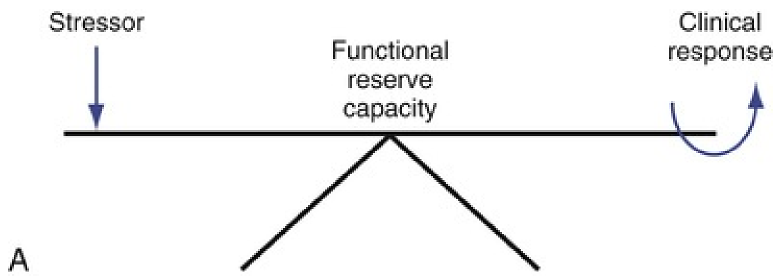
Global Implications for Urologic Health Care

As the population ages, there will be an increased need for health care providers with specific knowledge and skills to evaluate and treat clinical conditions in this heterogeneous and complex patient population. In many ways, urology is by its very nature, a geriatric specialty. Except for those who exclusively practice pediatric or adolescent urology, most urologists in general practice have a majority of patients in their practice who are more than 65 years old. **Urology consistently ranks among the top three specialties in the United States in terms of the total volume of older adults seen in clinical practice.** Only ophthalmology and cardiology outrank urology in terms of the total volume of geriatric care provided in the specialty (Drach and Griebling, 2003). There has been recommendation that geriatric competencies be incorporated into surgical training and included as part of board certification and continued maintenance of certification broadly across surgical disciplines (Bell et al., 2011). Surgical trainees have indicated that they are interested in learning more about geriatric care as part of their education (Shipway et al., 2015). As the medical workforce ages, there will be a growing need for more urologists with understanding and specific training on geriatrics principles (Gaither et al., 2016).

Epidemiologic studies have consistently shown that **incidence and prevalence rates for the most common urologic conditions tend to increase substantially with advancing age.** This includes urinary incontinence and lower urinary tract dysfunction, pelvic organ prolapse (POP), UTI, bladder outlet obstruction (BOO), and benign prostatic hyperplasia (BPH). With the exception of testicular cancers, all of the urologic malignancies have a predilection to occur in older adults. Sexual health problems are more common among older men and women than younger patients. **Increased population growth among older adults will mean that more elderly patients will develop urologic disorders,** and in turn will likely translate into increased rates of surgical care among geriatric patients (Takao et al., 2008). All of these factors contribute to the expanding need for expertise in geriatric urology (Drach and Griebling, 2003).

Clinical Evaluation of the Geriatric Urology Patient

Older adults frequently have more complex health needs compared with younger patients. This is in part due to changes associated with aging and to the increase in comorbidity seen in elderly patients. **Physiologic alterations associated with aging can lead to loss of functional reserve capacity,** which in turn leads to impaired response to stressors such as infection, surgery, chemotherapy, or other urologic conditions or treatments (Fig. 128.2). The concept of the body trying to restore or remain in balance in response to internal or external stressors has been termed *homeostasis*. In geriatrics, the decline in functional reserve capacity associated with aging is sometimes described using the term *homeostenosis*, an analogy to the narrowing of arteries with atherosclerosis. For a given stressor, older adults with lower baseline functional reserve capacity may not be able to respond as well or may actually have a more exaggerated response compared with younger patients with more reserve. An example would be the development and progression of a postoperative pneumonia. In a healthier younger patient, this may be relatively indolent and self-limited and may promptly resolve with appropriate antibiotic therapy. However, in a more debilitated older adult with less functional reserve capacity, the same level of pneumonia could result in a much more profound illness that could require more intense treatment and time to resolve. It could also have a higher likelihood of progression to more serious disease.



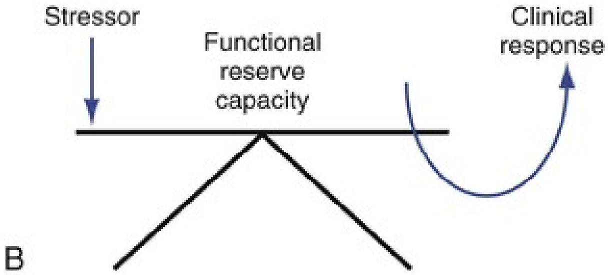


FIG. 128.2 Changes in functional reserve capacity with aging. With aging, there is a progressive decline in functional reserve capacity. This diagram demonstrates the conceptual model of homeostasis (A), in which the body tries to maintain balance in response to various stressors such as disease or clinical treatment. Progression to homeostenosis (B) is caused by relative decline in functional reserve capacity. In this case, response to identical stressors may be more difficult or complications more pronounced because of loss of functional reserve capacity.

One of the most commonly used measures of comorbidity is the **Charlson Comorbidity Index (CCI).** This was initially developed to identify underlying disease conditions that could help to predict subsequent mortality risk (Charlson et al., 1987). The instrument assigns points to each chronic condition, with a sum score indicating level of risk based on comorbidity. The CCI has been used extensively and has been validated for use in surgical patients. It has been applied recently to some urologic conditions such as kidney cancer to help make clinical decisions between surveillance and surgery in elderly patients (O'Connor et al., 2009). Self-reported health is an important predictive factor among geriatric patients. **Poor self-reported health among older adults has been linked to increased overall and disease-specific mortality and has in some cases been found to be a stronger negative predictor than physician-rated health status** (Giltay et al., 2012).

Because of this, older adults often require more involved clinical evaluation in relation to their urologic treatment. This includes a number of specific areas that are somewhat unique to geriatrics but that influence overall care for the patient. Development of comorbid chronic health conditions is common with aging. **The majority of adults over 65 years of age have at least one chronic medical condition, and more than 50% have at least two** (Wolff et al., 2002).

Functional Assessment

Functional assessment in geriatrics includes a number of components designed to evaluate reserve capacity and levels of dependence or independence. This includes evaluation of an older adult's ability to independently perform specific tasks. **A clear understanding of an individual patient's baseline functional status is vital to his or her care** (Dunlop et al., 2002). This provides a framework to better understand subsequent changes associated with surgery or other treatments. **Baseline functional status has been shown to be predictive of other health care outcomes,** including remaining life expectancy, morbidity, and mortality (Lubitz et al., 2003). There is wide heterogeneity among older adults, and this is not specifically related to chronologic age. Progression of clinical disorders and response to treatments can lead to changes in functional status, and the clinician must be able to identify these alterations compared with baseline function. The following components form the basic parts of functional assessment in geriatric patients.

Activities of Daily Living

Activities of daily living (ADLs) include basic tasks people need to do to function and interact in the world. These include bathing, dressing, grooming, use of the toilet, feeding, and physical ambulation. Each of these factors is evaluated on a scale ranging from complete independence to needing full assistance (Lawton and Brody, 1969). Alterations in ADLs are among the most predictive factors for need of caregiving assistance with aging. Although there can be variations in the pattern of progressive need for help with ADLs, bathing is typically the one for which people first need assistance. Feeding tends to be preserved the longest, even in people who are otherwise debilitated. A simple way to determine if people are beginning to need assistance with their ADLs is to ask if someone is able to shower or bathe independently. This can be an early sign of alterations in overall status that may be predictive of future change.

Instrumental Activities of Daily Living

The **instrumental activities of daily living (IADLs)** add a higher cognitive and executive function component to the basic ADLs. These include shopping, preparing food, housekeeping tasks, doing laundry, managing finances, using telephone or other communication devices, managing medications, and using transportation. As people age, it is common for them to need some assistance with the IADLs before they need help with ADLs, although there can be variation in these change patterns. Many community and home-based services are available to help with ADL and IADL needs as people age.

ADL and IADL function can be predictive of overall health status and future health variables. Using data from the Medicare Current Beneficiary Survey from 1992 to 1998, Lubitz et al. (2003) examined nearly 17,000 people aged 70 at the time of enrollment and studied longitudinal outcomes stratified by functional status. Those who were independent in all ADL and IADL variables had an estimated remaining life expectancy of 14.3 years and annual health care costs of $4600 (in 1998 dollars). Loss of independence in one IADL reduced expected remaining life expectancy to 12.4 years and increased annual health care expenditures to $8500. Needing assistance with at least one of the basic ADLs led to a reduction of remaining life expectancy to 11.6 years and increased annual health care expenditures to $14,000. These data clearly demonstrate that loss of functional independence is linked to reduced life expectancy and increased health care costs. Understanding baseline ADL and IADL function also helps clinicians to monitor changes in status over time and with treatments.

Mobility

Limitations in mobility can have a substantial impact on overall functional status for older adults. **Mobility impairment is frequently associated with urologic issues,** including the development of what is termed “functional” incontinence. In these cases, urinary incontinence is due to factors other than the bladder such as impaired mobility or cognition. Improvement in the underlying factors such as return of independent mobility could help to improve or resolve the urinary incontinence.

One of the most commonly used and well-validated clinical assessments for mobility is the **Timed Up and Go (TUG) test** (Podsiadlo and Richardson, 1991). To perform this test, the patients are seated in a stationary, hard-backed chair with arms. They are asked to stand, walk 3 m, turn, return to the chair, and sit down. If they normally use assistive devices such as a walker or cane for ambulation, they are allowed to use these. Most older adults without mobility limitations can complete this task in 10 seconds or less. More frail older adults who still maintain good mobility independence can complete this in 20 seconds or less. Inability to complete the test, or needing more than 20 seconds indicates a higher level of dependence for mobility. Although it seems simple, the TUG test measures a number of complex components associated with independent mobility. These include the ability to follow directions, quadriceps strength in standing from the seated position, gait, balance, and coordination. Diminished quadriceps strength is recognized as an early sign of decreased overall muscle function.

One of the newer conceptual models that expands on the complexity of the concept of mobility is the **Life Space Assessment** (Baker et al., 2003). This examines the degree to which a person is able to independently interact with his or her world. Measurements range from the extremes of being confined to one's bedroom to being fully able to travel and go out independently into the greater community and world at large. This can have important implications for urologic function. For example, people who are limited to their bedrooms may require complete assistance for toileting. An understanding of baseline life space capabilities also helps to better evaluate postoperative function in people undergoing surgery (Stewart et al., 2009).

Slower gait speed in elderly patients has been closely linked to reductions in remaining life expectancy, chronic disability, nursing home placement, and injurious falls (Hardy et al., 2007; Rothman et al., 2008). **It has been shown to be one of the strongest predictors of mortality and other negative health outcomes among older adults** (Seino et al., 2013). It is likely that this represents a marker condition that includes changes in other functional status components, including muscle strength and sarcopenia, nutritional status, and baseline levels of activity. Fatigue and easy exhaustion with physical activity are also associated with increased risk of mortality in elderly patients (Hardy and Studenski, 2008). These factors, including diminished levels of physical activity, a sense of easy exhaustion, and reduced gait speed, are clinical components of the frailty phenotype (Fried et al., 2001).

Cognition

Cognitive changes in older adults are common and can be acute or chronic. **An appreciation of baseline cognitive status for an individual patient is important, particularly in relation to changes that can be observed longitudinally over time, or directly related to various therapies.** Alterations in cognitive status may be associated with delirium or dementia, and recognition of these factors is important for correct diagnosis and subsequent treatment.

Various methods can be used to assess cognitive status. The most commonly used validated instruments include the **Folstein Mini-Mental State Examination (MMSE) and the Mini-Cog** (Borson et al., 2000; Folstein et al., 1975). Both instruments provide valuable information on the cognitive status of patients. The MMSE provides a brief cognitive assessment in several domains, including orientation, ability to follow directions, visual-spatial capacity, and short-term memory. It can be influenced by educational status, with more highly educated individuals tending to score higher at baseline. The instrument is graded on a scale from 0 to 30 with scores of 24 or less generally considered positive for dementia.

The Mini-Cog assesses ability to follow directions, visual-spatial cognition, and short-term memory and executive function. It is less influenced by educational level than the MMSE. Advantages of the Mini-Cog include ease of administration and shorter time required to complete assessment. It can usually be done within about 3 minutes and includes two components: a three-item short-term repetition with recall and a clock-drawing test. Subjects are asked to repeat and remember three words. These should be unrelated items and should not include abstract ideas, emotions, colors, or terms that modify or describe each other. Examples of words often used in testing are “apple, penny, and table.” These are also somewhat more complex because they each have two syllables. After patients attempt to repeat the words, they are asked to draw the face of a clock including all 12 numbers, and to set the hands to a specified time (usually 11 : 10). They may be provided with a paper that already includes the circle or they may draw the circle and complete the clock (Fig. 128.3). After they have finished drawing the clock, they are asked to repeat the three previously presented and repeated words. This concludes the test. Zero to three points are assigned for the short-term recall, one for each correctly repeated word. Either zero or two points are assigned for the clock drawing, depending on whether all components were correctly completed. A total score of 0 to 2 is positive for possible dementia, and a score or 3 to 5 is considered negative. The Mini-Cog has been validated in a variety of settings, does not require specialized equipment, is relatively quick and easy to administer, and is less influenced by language and educational status compared with other available tests.

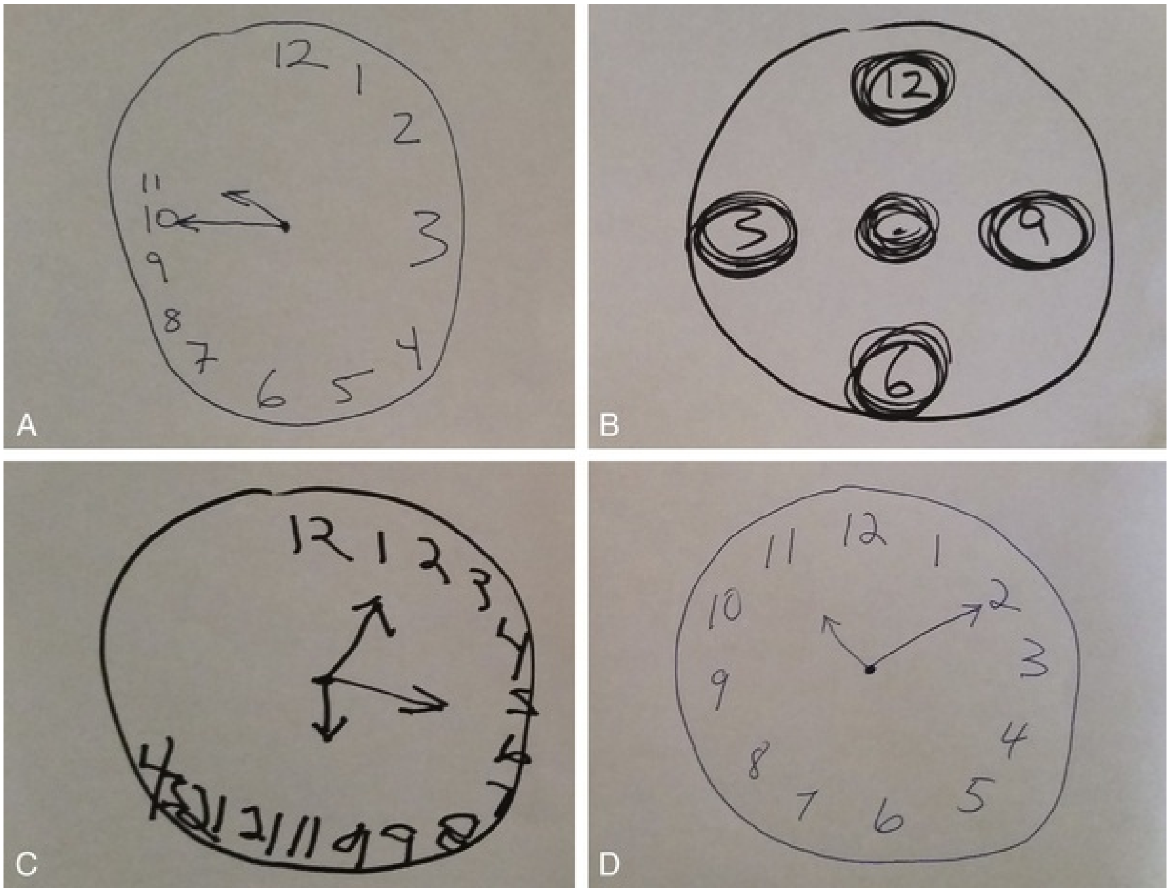

FIG. 128.3 Mini-Cog clock drawing test results (abnormal and normal). Examples of the clock drawing test from the Mini-Cog assessment. (A) Abnormal: Note the incorrect spatial orientation of the numbers and placement of the hands. (B) Abnormal: Only four numbers are included and no hands are drawn to show time. Note the perseveration on drawing the circles around the numbers. (C) Abnormal: Note the incorrect spatial orientation of the numbers, repetition of part of the numerical sequence, and incorrect number and placement of hands. (D) Normal: Note the correct spatial orientation of the numbers and placement of the hands to indicate time per the instructions.

Understanding preoperative cognitive function is important for several reasons. It can help gauge the capacity for patients to provide informed consent for treatment and as a comparison for later observed cognitive status. **Advanced directives and informed decision making regarding health care are an important part of geriatric practice.** Reduced baseline cognitive function has been associated with worse postoperative outcomes in elderly surgical patients. Examples include a higher incidence of delirium (78% vs. 37%; $P < 0.001$), longer hospital stays (15 ± 14 vs. 9 ± 9 days; $P = 0.008$), higher rate of discharge institutionalization (42% vs. 18%; $P = 0.001$), and higher 6-month mortality

(13% vs. 5%; *P* = 0.040) (Robinson et al., 2012).

Potentially reversible causes of memory loss in patients should be considered and addressed if appropriate. Conditions commonly seen in urologic practice include vitamin B_{12} deficiency, hypothyroidism, and medication side effects. Patients with a history of urinary diversion using small intestine can be at particular risk for vitamin B_{12} deficiency, and replacement therapy may be necessary. Although not necessarily reversible, tertiary neurosyphilis can be associated with memory loss and neurogenic bladder and voiding dysfunction.

Depression

Depression is a very common condition among older adults. Like other conditions, the incidence and prevalence increase with advancing age, but depression should not be considered a normal or expected part of the aging process. A number of **urologic health conditions have been associated with increased rates of depression, including urinary incontinence and various genitourinary malignancies.** The **Geriatric Depression Scale (GDS)** is a short, validated screening tool to assess for possible depression in older adults (Sheikh and Yesavage, 1986). The instrument consists of 15 items with yes/no responses. A score of 0 to 2 points is considered normal. If someone scores 3 or more points, the screening test is considered positive for possible depression. This could alert the provider to the potential need for additional evaluation. Input from the patient's primary care provider or consultation with either a geriatrician or geriatric psychiatrist may be indicated.

Examples of urologic conditions that occur at higher rates in geriatric patients and tend to be associated with risk for depression include urinary incontinence, POP, prostate cancer, and sexual dysfunction (Kafri et al., 2013; Kahn et al., 2013; McCabe and Althof, 2014; Ravi et al., 2014). Urinary incontinence has been shown to be undertreated in the general older adult population and has substantial negative effects on multiple health domains (Chang et al., 2008). Additional research is needed to identify the role of treatment of urologic conditions on mental health outcomes.

Surgical Risk and Medical Optimization

Surgical therapy remains one of the mainstays of urologic treatment for many of the clinical conditions that affect geriatric patients. Unfortunately, many clinicians and patients seem to have an inherent bias against surgical therapy for older adults. However, **with careful planning, surgical therapy may be an appropriate option for treatment of many urologic conditions seen in older adults.** The development of minimally invasive surgical techniques has opened up a new avenue for potential therapy for many patients. Age by itself should not be a limiting factor, and in most cases clinical comorbidity is a much more influential issue. However, even in these cases, careful preoperative planning and medical optimization can potentially reduce risk of complications after urologic surgery (Takao et al., 2008).

One of the primary tasks of the urologic surgeon planning operative care for a geriatric patient is to identify potential risks and benefits associated with surgery. **Preoperative optimization should be carefully considered.** Although it is technically not possible to "clear" someone for surgery, there are a wide variety of steps that can be taken to optimize health status in different realms before surgery. The American College of Surgeons and the American Geriatrics Society (AGS) recently collaborated on a project to help outline evaluations that should be used before surgery in older adults and in the perioperative period (Chow et al., 2012; Mohanty et al., 2016). These recommendations are grounded on evidence-based data regarding evaluation of each organ system and various functional components. The goals of these evidence-based recommendations are to help identify risks and improve status before surgical intervention. This includes several targeted components in addition to basic functional assessment with ADLs, IADLs, cognitive status, and mobility that have been previously described (Box 128.1; Chow et al., 2012). Data obtained from the National Surgical Quality Improvement Program were used to construct recommendations highlighted in this document. A more recent publication has focused on perioperative optimization (Mohanty et al., 2016). Specific activities that can promote improved outcomes are highlighted in Box 128.2. Ongoing research has enhanced and optimized these types of data sets to maximize information that can be used in developing optimal models of surgical care for older adults (Berian et al., 2017).

Box 128.1

Preoperative Assessment Recommendations for Older Adults

- Assess cognitive ability and capacity
- Screen for depression
- Identify risk factors for delirium
- Screen for alcohol and other substance use
- Cardiac evaluation (American College of Cardiology/American Heart Association)
- Pulmonary risk assessment
- Document functional status and risk of falls
- Determine baseline frailty score
- Assess baseline nutritional status (consider preoperative replacement/supplementation)
- Detailed medication history and monitor for polypharmacy
- Determine patient's treatment goals and expectations
- Determine familial and social support systems
- Order appropriate diagnostics tests/labs as clinically indicated

Modified from Chow WB, Rosenthal RA, Merkow RP, et al.: Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 215:453–466, 2012.

Box 128.2

Optimal Perioperative Management of the Geriatric Patient

Immediate Preoperative Management

Discuss goals of care and treatment preferences with patients and family
Ensure geriatric patients have advance directives in place
Consider early palliative care consultation for those with poor prognosis (especially if <6 months estimated remaining life expectancy)
Carefully consider the times for preoperative fasting based on type of surgery and types of food or fluids

Ensure careful medication review

Intraoperative Management

Collaborate closely with anesthesia colleagues to optimize choice of anesthetic type

Judicious management of intraoperative status (e.g., fluids, temperature, positioning)

Peri- and Postoperative Management

Analgesics should be administered based on patient-specific needs and indications

Preventive treatment and management of nausea and vomiting to help avoid aspiration risk

Screen and monitor for delirium or other cognitive changes

Implement strategies to prevent postoperative pulmonary complications

Assess for fall risk and implement fall prevention strategies

Evaluate fluid and nutritional status, particularly in those with perioperative dietary restrictions, and provide replacement as clinically indicated

Employ methods to reduce risk of urinary tract infection (e.g., remove catheters as soon as possible)

Implement measures to prevent functional decline such as early mobilization and referral to physical therapy

Assess for pressure ulcer risk and implement multicomponent interventions for prevention and treatment

Engage the patient, family and caregivers, and social services and nursing staff in planning for transitions of care

Modified from Mohanty S, Rosenthal RA, Russell MM, et al.: Optimal perioperative management of the geriatric patient: a best practices guideline from the American College of Surgeons NSQIP and the American Geriatrics Society. *J Am Coll Surg* 222:930–947, 2016.

Chronologic age is usually not identified as an independent risk factor in most research examining morbidity and mortality outcomes from surgery.

However, extensive surgical time and poor baseline ASA classification status have been linked to worse outcomes in elderly urologic surgical patients (Peled et al., 2009). In addition, compared with elective cases, urgent and emergent surgical procedures have been shown to be associated with greater overall morbidity and mortality among geriatric patient undergoing urologic surgery (Peled et al., 2009).

Nutritional assessment is important for overall health and wound healing. One problem is that no single measure has proven adequate for complete preoperative assessment (Griebling, 2004). Different questionnaires and various biomarkers have been used. Albumin and prealbumin measure protein nutrition and are the most commonly used serum markers. Data on preoperative nutrition supplementation in geriatric patients have been variable (Evans et al., 2014). One question is if improved nutrition can help contribute to pressure ulcer prevention (Hill-Brown, 2011). Although nutrition is a contributor to this condition, other factors such as tissue pressure and shear forces may play a stronger role. Good nutrition does appear to influence wound healing (Jaul, 2010; Rosenthal, 2004). Postoperative wound infections are a common and often preventable complication of surgery in older adults. They tend to increase length of hospital stay and associated costs. **Elderly surgical patients who experience a surgical site infection have been found to have a 3.5 times greater risk of mortality compared with those who do not develop this type of infection** (Kaye et al., 2009). The Centers for Medicare and Medicaid Services (CMS) have included surgical site infections as one of the “never events” for which hospitals will not be reimbursed. Diminished functional status has been shown to be associated with an increased risk of surgical wound infections (Chen et al., 2010). This is likely due to a reduction in overall functional reserve capacity, which is associated with changes in immunity and other organ system response.

Postoperative urinary retention is another very common problem that occurs frequently in geriatric patients. A wide variety of factors can increase the risk for postoperative urinary retention, including medication effects, opioid narcotics, decreased mobility, delirium, cognitive impairment, and a history of pre-existing lower urinary tract anatomic and functional issues. Correction of the underlying cause often leads to resolution of the problem, and time is an important factor in many cases (Darrah et al., 2009; Johansson and Christensson, 2010).

Anesthesia

Anesthetic considerations are important in planning for surgical interventions in geriatric urologic patients. Patients often ask is if regional anesthesia would be a safer alternative compared with general anesthesia. Most studies have not shown significant differences in either morbidity or mortality among older adults undergoing surgery using regional blocks versus general anesthesia (Mason et al., 2010; Tognoni et al., 2011).

Other important anesthetic considerations include thermoregulation during surgery, fluid balance, and patient positioning. **Hypothermia during noncardiac surgery increases risk for cardiovascular and thromboembolic events,** including myocardial infarction, deep vein thrombosis, and stroke. Intraoperative hypothermia has also been associated with risk of postoperative wound infection (Leeds et al., 2014). Maintenance of appropriate intraoperative patient temperatures has been identified as an essential goal and is one of the variables that is tracked for quality of hospital care in the United States. Proper fluid balance is also important, and care must be taken to avoid fluid overadministration, which can induce pulmonary edema or congestive heart failure in older adults. Patient positioning requires careful attention to padding pressure points to prevent neuropathy and adjusting to limitations in joint flexibility in patients with arthritis (Akhavan et al., 2010; Rozet and Valilala, 2007). Positioning patients awake before induction of anesthesia can be useful in these circumstances to prevent injury.

Cognitive changes are frequently seen immediately after anesthesia in geriatric patients. Reported rates can be as high as 56%, with 25% still having some change compared with baseline at 3 months after general anesthesia (Price et al., 2008). Although this usually resolves, in some cases cognitive changes can be more prolonged. Among older adults undergoing noncardiac surgery, advancing age, history of stroke, and lower baseline educational levels have been associated with postoperative cognitive decline (Monk et al., 2008).

Prehabilitation

Recent research has examined the potential utility of preoperative conditioning and strength-building exercise in older adults. Termed *prehabilitation,* these efforts focus on improving overall conditioning, stamina, and endurance for activity. This may help to improve or at least slow the decline in functional reserve capacity. Nutritional interventions generally focus on improving protein reserves before surgical intervention. **General assessments or "eyeballing" the patient to determine level of frailty may not be adequate, and more precise measures are useful for preoperative evaluation of risk** (Hubbard and Story, 2014). Preoperative interventions have shown mixed results, and additional research will be necessary to identify optimal targets for intervention and appropriate candidates for these types of treatments.

Comprehensive Geriatric Assessment

Comprehensive geriatric assessment (CGA) is a structured method of complete health care analysis for older adults. This type of evaluation is usually conducted by a geriatrician specialized in the primary care of older adults in conjunction with other multidisciplinary health care providers, including nurses, pharmacists, social workers, physical and occupational therapists, and others. Some primary care practitioners may offer CGA as part of their clinical care for geriatric patients. **Consultation and partnering with a geriatrician** in care of older adults with complex medical problems can help facilitate what can sometimes be a complex process. Similarly, **working with anesthesiology colleagues** for preoperative assessment can help to clarify clinical needs and choices of anesthetic technique in an attempt to optimize care.

There is great interest in the role of expanded assessment of geriatric patients undergoing major surgery and influence on subsequent outcomes. One study of 62 elderly women undergoing pelvic floor reconstructive surgery showed no statistically significant difference in multiple outcomes between those randomized to an enhanced CGA and those who underwent routine preoperative evaluation (Richter et al., 2005). However, the researchers noted that this may have been due to the overall high functional and health status of women in this study. Studies with more frail and functionally impaired older adults may yield different results. Information gleaned from CGA has been shown to be predictive of morbidity and mortality risk after surgery (Kim et al., 2013). Geriatric patients undergoing radical cystectomy have been found to have increased complications and length of hospital stay related to underlying comorbidity and functional limitations that can be identified on careful preoperative assessment (Prentis et al., 2013). Additional research on this topic will help to elucidate the most important factors that should be included in these types of evaluations to help optimize outcomes in geriatric surgical patients.

Major Geriatric Syndromes and Urology

“Geriatric syndromes” are defined as conditions that are complex in nature, tend to occur more commonly among older adults, are typically multifactorial, and can have substantial clinical or other outcomes for affected patients. Successful prevention or treatment often requires a multicomponent approach. Examples of geriatric syndromes include frailty, falls, pressure ulcers, polypharmacy, delirium, and urinary incontinence. Different syndromes can interact and influence each other. For example, frailty is linked to falls, and both conditions are closely associated with urinary incontinence. Each of these syndromes can have direct and indirect effects on urologic health in older adults (McRae et al., 2014). Data from the Health and Retirement Study on more than 11,000 older adults living in the community and nursing homes demonstrated that 49.9% had at least one geriatric syndrome, and presence of multiple geriatric syndromes was common (Cigolle et al., 2007). Prevalence rates for geriatric syndromes are particularly high in homeless older adults who may be vulnerable overall (Brown et al., 2017). Geriatric syndromes strongly increased risk of dependency on others for completion of ADLs even after controlling for demographic factors and chronic diseases. One geriatric syndrome led to an adjusted risk ratio of 2.1 (95% confidence interval [CI], 1.9–2.4), for two syndromes this increased to 3.6 (95% CI 3.1–4.1), and for three or more syndromes 5.6 (95% CI 56–7.6). In a cross-sectional analysis of 12,480 older adults, prevalence of geriatric syndromes among those with cancer was 60.3% compared with 53.2% in those without a history of cancer ($P < 0.001$) (Mohile et al., 2011). This highlights the complexity of these conditions and overlap with other health issues associated with aging.

Frailty

Frailty is a complex condition frequently seen in elderly patients that is becoming better understood with ongoing research. It is not age dependent and can also occur in younger people, although incidence and prevalence increase with advancing age. **It overlaps but is not completely identical to the concepts of comorbidity or disability** (Fig. 128.4). Comorbidity refers to presence of other health states or conditions. Examples include diabetes or hypertension. Disability refers to need for assistance from others to accomplish various tasks. An example would be the need to have someone help with bathing, dressing, or using the toilet. Potential relationships between preoperative frailty and postoperative outcomes have recently garnered increased research attention (Revenig et al., 2013).

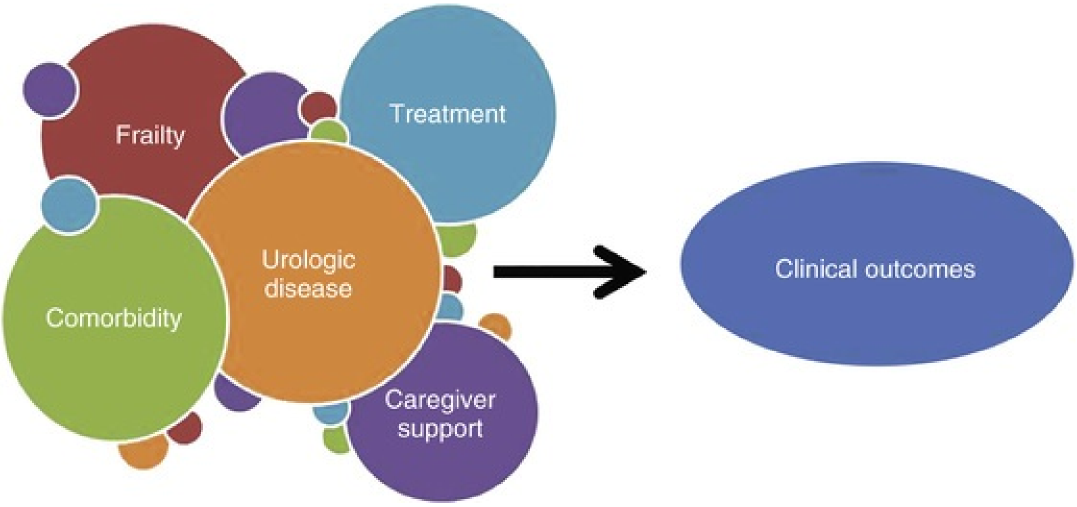

FIG. 128.4 Conceptual model of health complexity and clinical outcomes in geriatrics. This schematic highlights the interrelated nature of urologic disease, comorbidity, frailty, treatment, caregiver support, and other variables. Note that these are related and influence each other but are distinct entities that do not completely overlap. Numerous other factors can contribute and interact with these variables to influence overall clinical outcomes.

Several different definitions and conceptual models of frailty exist, and these differ somewhat based on theoretical components they include. One causation theory is an accumulated deficits model. In this conceptual framework, multisystem deterioration is combined with reduced functional reserve capacity. Accumulated deficits can be counted numerically, and increased summative scores indicate a higher degree of frailty. In this model, frailty tends to progress with cyclic deterioration over time and with more added deficits. The Deficit Accumulation Index (DAI) has been used in an attempt to identify preoperative levels of frailty and predict subsequent outcomes (Braden and Bergstrom, 1994; Cohen et al., 2012). However, DAI has not been found to be statistically predictive of outcomes in this study. This indicates a simple numeric scoring of deficits may not be adequate, and interactions between components are more complex.

Although different operational definitions of frailty have been proposed, one of the more commonly used is the conceptual model developed by Fried et al. (2001), which includes measurable changes for five different components. **This frailty phenotype includes unintentional weight loss of more than 10 pounds or more than 5% of total body weight in 1 year, reduced grip strength, slowing of gait speed and mobility, decreased overall levels of activity, and a sense of easy exhaustion with activity.** Individuals with three or more components are considered “frail,” those with one or two components are classified as “pre-frail,” and those with none of the components are “non-frail.”

The predictive value of frailty assessment in older urologic patients, particularly those being considered for surgery, has been the subject of recent research. Frailty evaluation can be accomplished relatively easily in outpatient clinical settings, and results can be predictive of morbidity and mortality outcomes in elderly surgical patients (Kim et al., 2014; Makary et al., 2010; Ravaglia et al., 2008). Data derived from electronic medical records can be used, although this may not provide complete information in all cases (Amrock et al., 2014). Inclusion of cognitive changes in addition to physical assessment has been shown to improve predictive value for clinical outcomes among hospitalized older adults (Wou et al., 2013). Frailty has been associated with substantial increased risk of developing new-onset incontinence among hospitalized patients (Chong et al., 2018)

Translational research studies have attempted to identify a relationship between various inflammatory biomarkers and the frailty phenotype. Increased levels of IL-6, d-dimer, C-reactive protein, white blood cell count, and others have been described in correlation with increased frailty (Chang et al., 2012; Fontana et al., 2013). There is some debate over whether low levels of inflammatory response may actually be beneficial, particularly for wound healing, but that higher levels may be destructive because of oxidative stress.

Delirium

Delirium is an extremely important geriatric syndrome to consider in older urologic patients. **Delirium is defined as an acute confusional state characterized by fluctuations in mental status and inattention. In addition, patients must exhibit either disorganized thinking or an altered level of consciousness.** This most commonly manifests in the form of agitation; however, a hypoactive form can also occur. Patients may experience hallucinations or delusions. These symptoms can be disturbing to patients, loved ones, and clinical care providers. Agitated patients tend to act out physically or emotionally, and the behavior can usually be easily recognized. The hypoactive form of delirium can be much more subtle and difficult to diagnose. However, data suggest that hypoactive delirium actually may be more dangerous in terms of negative sequelae, including risk for mortality (DeCrane et al., 2011).

Delirium is highly prevalent and is associated with substantial negative outcomes. However, the condition is often underrecognized in this population

(Vollmer et al., 2010). **Rates of developing postoperative delirium range from 10% to 15% after noncardiac surgery and increase in cases of either urgent or emergency surgical procedures** (Demeure et al., 2006). **Patients who develop delirium postoperatively have a two- to threefold increase in the risk of mortality within the first year after surgery** (Ely et al., 2004; McCusker et al., 2002). There is also an increased risk of progressive cognitive decline and potential need for placement in nursing home care at the time of hospital discharge in patients who develop an episode of delirium (Popejoy et al., 2013; Rudolph et al., 2008).

There are multiple risk factors for development of delirium in geriatric patients, including around the time of surgery (Tai et al., 2015). Examples include electrolyte abnormalities, pain, sensory impairment, immobility, dehydration, sleep deprivation, pneumonia or other infections, and alcohol withdrawal. Having had a prior episode of delirium is also a strong risk factor for future delirium. Patients with underlying dementia are also at higher risk. Acute UTIs in older adults may be a cause for delirium, and urinary samples including cultures should be checked as part of the evaluation if this is suspected (Eriksson et al., 2010). In a study of urologic surgical patients, poorer baseline functional status and older age were identified as risk factors for delirium, but type of anesthesia (regional vs. general) and mode of surgery (open vs. endoscopic) were not (Tognoni et al., 2011). Some medications, including statins, have been identified as another potential risk factor in surgical patients (Redelmeier et al., 2008).

Inoyue and colleauges developed and validated the Confusional Assessment Method (CAM) as a way to identify and diagnose delirium (Inouye et al., 1990). These diagnostic criteria require that patients exhibit an acute change in mental status with a fluctuating course and inattention. In addition, they must also exhibit either disorganized thinking or an altered level of consciousness. The CAM has been used in numerous clinical settings and has been shown to be easy to use and interpret. Using these criteria, delirium can be diagnosed with a 94% to 100% sensitivity and a 90% to 95% specificity (Inouye, 2006).

Several studies have examined the effects of delirium on clinical outcomes in older adults including those developing the condition after surgery. In one study of 49 geriatric patients undergoing radical cystectomy, the incidence of postoperative delirium was 29%, and readmission and reoperation rates were higher in those who developed delirium compared with those who did not (Large et al., 2013).

Prevention of delirium is key, and clinicians should have a high index of suspicion for diagnosis in patients who exhibit signs or symptoms of the condition. Some medications are known to substantially increase the risk of delirium in older adults, including sedative hypnotics, anticholinergics, and opioid narcotics. Care must be taken to control pain but also avoid inducing delirium caused by medications. Pain is a risk factor for development of delirium, and this must be carefully assessed and managed. In patients with underlying cognitive impairment such as dementia, pain can be difficult to assess accurately (Horgas et al., 2009). Patient-controlled analgesia (PCA) offers the potential benefit of avoiding overdosing of medication, provided only the patient is pushing the dosing button on the device. However, proper use of a PCA requires a cognitively intact patient who understands the therapy and is able to self-administer medication when needed to control pain.

Treatment for delirium includes methods to reduce disruption and improve sensory interaction with the patient and his or her surroundings. This includes maintaining proper sleep-wake cycles, minimizing distractions including alarms and other loud noises, having family or other loved ones at the bedside to help reorient the patient, making sure a patient's hearing aids and glasses are provided, and assisting with mobility. Underlying fluid and electrolyte imbalances should be corrected. In patients who present a physical danger to themselves or care workers, temporary physical or chemical restraint may be necessary. **The preferred medication treatment is haloperidol administered intravenously in small doses, usually starting at 0.25 or 0.5 mg.** Doses may be repeated at approximately 15-minute intervals until the patient is calm. A total dose of 1 to 2 mg or more may be required, but it is safer to administer this in progressive small quantities and monitor for response rather than giving a large bolus dose, which could be too sedating. Other benzodiazepines or sedative hypnotics should generally be avoided because of potential adverse effects, including worsening of delirium, severe sedation, or an increase in associated delusions or hallucinations. Physical restraints should be used only with extreme caution and for short time periods and are indicated only if patients are in imminent danger of harming themselves or others.

Costs associated with postoperative delirium in geriatric surgical patients are high. Development of delirium, even subsyndromal delirium, is associated with increased rates of hospital readmission, reoperation, caregiver requirements, and need for institutionalization (Cole et al., 2008; Large et al., 2013). Economic analysis has shown an approximately 2.5-fold increase in costs for elderly patients who experience an episode of delirium while in the hospital compared with those who do not develop delirium (Leslie et al., 2008).

Falls

Older adults are at an increased risk for falls and associated injuries, including long bone and hip fractures. **Urinary incontinence and use of indwelling urinary catheters have been identified as risk factors for potentially injurious falls** (Brown et al., 2000; Chiarelli et al., 2009; Foley et al., 2012). In addition, there have been data suggesting a potential association between anticholinergic use and falls in elderly women (Marcum et al., 2016). LUTS including overactive bladder have been shown to increase fall risk in community-dwelling older adults and those requiring home care services (Hunter et al., 2013; Kurita et al., 2013). In long-term care facilities, urinary incontinence and behavioral changes associated with cognitive decline and dementia have been identified as independent risk factors for falls in older adults (Hasegawa et al., 2010). Nocturia can also play a role (Galizia et al., 2012). Contributing clinical and environmental factors include orthostatic or postural hypotension, vertigo, gait and balance problems, poor lighting, physical obstacles, or long distance between the bed and toilet. Urinary urgency is a common risk factor for falls because of nocturia or urgency UI. When older adults attempt to rush to the toilet, fall risk increases. Slipping on wet floors caused by urine leakage can also occur. Additional identified risk factors for falls include visual and other sensory impairments, alterations in cognitive status, and delirium.

Urinary catheters have been shown to increase risk of falls in older adults. Similarly, other **physical restraints** have been associated not only with increased falls but also with other potentially dangerous injuries including strangulation and accidental death. **Physical restraints should be avoided if at all possible,** and efforts targeted at reducing their use have been beneficial in nursing home and other care settings. Other interventions designed to improve overall care in long-term care facilities have also been shown to improve outcomes and decrease risk of falls associated with urinary incontinence in this setting (Min et al., 2011).

Elderly men on androgen deprivation therapy are at particularly increased risk for fractures and other injuries associated with falls (Bylow et al., 2008). Hormonal manipulation with androgen deprivation is associated with decreases in bone mineral density and an increased risk of development of osteopenia and osteoporosis. This causes bones to be more brittle and increases risk of fracture during falls. Elderly men with associated LUTS resulting from BPH or other conditions have been shown to have higher rates of falls and fractures compared with men without these urologic conditions (Parsons et al., 2009).

Pressure Ulcers

Pressure ulcers are areas of localized tissue necrosis that typically occur over bony prominences because of prolonged pressure against a hard surface. Tissue shearing can also occur with movement and transfers. Changes in skin anatomy and integrity occur as a part of the general aging process with a decrease in the amount of elastic tissue and alterations in collagen and other connective tissue quality. In addition, older adults often have decreased sensation in cutaneous tissues and may be prone to increased rates of underlying skin infections. These factors increase the risk of pressure ulcer formation in older adults. **Urinary incontinence is another common factor that increases pressure ulcer risk in older adults.** Maceration of tissues resulting from chronic moisture can lead to progressive tissue loss, particularly when combined with physical pressure or shearing forces.

Positioning and transfers during surgery in older adults are especially important. Care must be taken to adequately pad all pressure points during surgery, and efforts made to eliminate shearing effects during transfers between beds and transport carts. Many older adults suffer from arthritis, and this can make positioning for surgery challenging, particularly in the dorsal lithotomy position. In these cases, positioning the patient while awake before induction of anesthesia can be useful to help confirm a comfortable position and prevent injury.

Early mobilization and physical activity after surgery are important for many reasons, including reducing the risk of pneumonia, deep vein thrombosis, pulmonary embolus, and pressure ulcers. Even among healthy younger people, extended bed rest is associated with substantial loss of mobility, aerobic capacity, and lower extremity strength (Coker et al., 2015; Kortebein et al., 2008). These negative effects are compounded in older adults, who may start at diminished baseline functional levels. Frequent turning of patients who are in bed or using a wheelchair is another important prevention method. Use of specialized air mattresses or other pressure reduction methods also helps reduce risk.

Pressure ulcers are staged based on clinical characteristics. Stage I ulcers include nonblanching erythema of intact skin. Stage II ulcers include partial thickness skin loss but do not involve muscle or other deeper tissues. These can appear as an abrasion, blister, or shallow crater. Stage III ulcers involve full-thickness skin loss, which may extend to but not through the underlying fascia. Stage IV ulcers are characterized by extension into deeper tissues, including muscle or bone with possible exposure of supporting structures such as tendons.

It is important to carefully document skin integrity in older adults being admitted to hospital care. The CMS have designated new pressure ulcer formation as one of the “never events,” which is considered preventable in essentially all cases. As such, they will not reimburse facilities or providers for care for new pressure ulcers.

The prevalence of pressure ulcers among hospitalized elderly patients has been reported to be as high as 8.9% (Barrois et al., 2008). **Urinary, fecal, and dual incontinence have been identified among the strongest risk factors for the development of pressure ulcers in the elderly population.** Clinicians should have a high index of suspicion for the risk of pressure ulcers, and careful examination should be performed as part of the routine physical examination in older adults with bladder and bowel incontinence. Among hospitalized older adults, increased length of time waiting in the emergency room, immobilizing procedures or medications, and intensive care unit stays have been identified to increase the risk of developing pressure ulcers (Baumgarten et al., 2008).

Polypharmacy and Medication Optimization

Polypharmacy is a highly prevalent and complex geriatric syndrome that has been defined in a number of different ways. The simplest definition is the use of multiple medications. More recent definitions include the concepts of increased regimen complexity and use of potentially inappropriate medications. More complex medical regimens may be difficult for older adults to follow correctly and can lead to poorer compliance with prescribed therapy. Risk of drug interactions increases exponentially with increased numbers of medications. Use of inappropriate medications can lead to untoward side effects and other negative outcomes (O'Connor et al., 2012). Rates of potentially inappropriate medication prescription among older adults are high, with approximately 25% of more than 272,000 in one study being on these types of drugs in the perioperative period (Finlayson et al., 2011). The ultimate goal is to optimize pharmacotherapy and minimize risk in older adults using medications. **The practice of medication reconciliation during hospitalization and clinical evaluation has become a**

common practice and is an important step in helping to reduce or eliminate polypharmacy in geriatric patients. During this process, all medications including prescription and non-prescription medications are assessed. Clinical indications for each medicine are verified, and response determined. Ideally, medications without a clear clinical indication should be discontinued. Potentially inappropriate medications should also be identified, and safer agents substituted if possible. In addition, medication underuse can occur with elderly patients, and it is important to recognize when medications may be clinically indicated based on guidelines or other evidence-based practice.

In 1993 the late Dr. Mark Beers convened a consensus panel to develop a list of potentially inappropriate medications for use in older adults in nursing home settings. This original list has been updated and expanded to include all older adults and is no longer limited by location or type of clinical care. **The AGS has recently published a revised version of the Beers criteria** (American Geriatrics Society Beers Criteria Update Expert Panel, 2015). This is a highly evidence-based document that categorizes medications into different groups based on characteristics and considerations for use in older adults. The most recent version includes information regarding level of evidence used to make recommendations, and overall strength of the recommendation from the expert panel. This document is being maintained and updated on a regular basis as new data emerge. It is important that urologists be familiar with the Beers criteria and the concept of potentially inappropriate medications (PIMs). This can help them to make more informed decisions about medication use in older adults, which can help improve the care they provide (Griebling et al., 2016; Steinman et al., 2015). Identification of alternate medications or treatment strategies may be helpful in this regard (Hanlon et al., 2015).

Some medications are considered always inappropriate for elderly patients and should be avoided in all cases. An example of such a medication often used in urologic practice is meperidine (Demerol). This drug was included because of the significant potential risks for delirium and other adverse events caused by accumulation of a toxic metabolite, poor overall efficacy, and availability of other more clinically useful alternatives. Other urologic medications are included in portions of the AGS Beers criteria document. For example, antimuscarinic agents used in treatment of overactive bladder (OAB) and urgency UI are included in a group of medications to avoid with specific comorbid conditions. In this case, these medications should be avoided or used with caution in older adults with a history of chronic constipation or cognitive impairment. Nitrofurantoin is included as a medication to avoid in older adults with impaired renal function (GFR < 30 mL/min) or for chronic prophylaxis resulting from the potential risk of pulmonary fibrosis. It is acceptable for treatment of acute UTIs and other short-term indications in patients with adequate renal function. A summary of medications commonly used in urologic practice included in the 2015 AGS Beers criteria is presented in Table 128.1.

TABLE 128.1

Select Medications Commonly Used in Urology Included in the 2015 Beers Criteria

MEDICATION	RECOMMENDATION	RATIONALE	QUALITY OF EVIDENCE	ST R
Peripheral α_1 blockers • Doxazosin • Prazosin • Terazosin	Avoid use as an antihypertensive (all patients) Avoid use in women with stress UI	Not recommended as routine treatment for hypertension; alternative agents have superior risk/benefit profile; high risk of orthostatic hypotension; may aggravate stress UI in women	Moderate	St
Nitrofurantoin	Avoid for long-term antibacterial suppression Avoid in patients with CrCl < 30 mL/min	Safer alternatives available; potential for pulmonary toxicity hepatotoxicity, and peripheral neuropathy; lack of efficacy in patients with CrCl < 30 mL/min because of inadequate drug concentration in urine	Low	St
Tertiary tricyclic antidepressants, alone or in	Avoid	Highly anticholinergic, sedating, and cause	High	St

combination • Amitriptyline • Imipramine		orthostatic hypotension		
First-generation antihistamines (as single agent or as part of combination products) • Diphenhydramine (oral) • Hydroxyzine • Promethazine	Avoid	Highly anticholinergic clearance reduced with advanced age, and tolerance develops when used as a hypnotic; anticholinergic effects and toxicity. Use of diphenhydramine in special situations such as acute treatment of severe allergic reaction may be appropriate	Moderate	St
Androgens • Methyltestosterone • Testosterone	Avoid unless indicated for confirmed moderate to severe hypogonadism with clinical symptoms	Potential for cardiac problems and contraindicated in men with prostate cancer	Moderate	W
Estrogens with or without progestins	Avoid oral or topical patch; Topical vaginal cream is acceptable use for management of dyspareunia, lower urinary tract infections and other vaginal symptoms	Evidence of carcinogenic potential (breast and endometrium) and aggravation of UI for oral or transdermal; lack of cardioprotective effect and cognition protection in older women Evidence that vaginal estrogens for treatment of	High: oral and patch Moderate: topical	

		vaginal dryness is safe and effective in women with breast cancer, especially at dosages of estradiol < 25 mcg twice weekly		
Anticholinergics Benzodiazepines (short and long acting)	Avoid	Older adults have increased sensitivity to this class of drugs; decreased metabolism of long-acting agents can induce or worsen delirium, falls, fractures	Moderate	St
Meperidine	Avoid as an analgesic, especially in individuals with chronic kidney disease	Not an effective oral analgesic in commonly used doses; may have higher risk of neurotoxicity including dementia than other opioids; safer alternatives available	Moderate	St
Oral antimuscarinics for UI • Darifenacin • Fesoterodine • Oxybutynin (oral) • Solifenacin • Tolterodine • Trospium	Be aware of anticholinergic properties and potential effects	Potential anticholinergic effects may include dry mouth, constipation, confusion, etc.		
Desmopressin	Avoid for treatment of nocturia or nocturnal polyuria	High risk of hyponatremia; safer alternative treatments available	Moderate	St

Note: This is not a complete listing of all medications included in the 2015 Beers criteria.

BPH, Benign prostatic hyperplasia; *CrCl,* creatinine clearance; *LUTS,* lower urinary tract symptoms; *UI,* urinary incontinence.

Modified from American Geriatrics Society (AGS) Beers Criteria Update Expert Panel: American Geriatrics Society updated Beers criteria for potentially inappropriate medication use in older adults. *J Amer Geriatr Soc* 63:2227–2246, 2015. Please see this source for detailed information.

Medications with anticholinergic effects deserve special mention. There are a large number of different medications that can have potential anticholinergic effects in older adults. This is due in part to cross-reactivity between different types of receptors located in different organs including salivary gland, bowel, and bladder. Common anticholinergic effects in older adults include dry mouth, constipation, dry eye, and confusion. Serum studies have shown total anticholinergic burden can be measured, although lists of medications must be used in conjunction with this to improve diagnostic accuracy (Lampela et al., 2013). Increased anticholinergic burden can worsen underlying cognitive function, memory, and associated comorbid conditions such as Alzheimer disease (Fox et al., 2011a, 2011b; Han et al., 2008; Koyama et al., 2014). Increased anticholinergic load has been associated with increased risk of mortality and decline in physical function (Fox et al., 2014). It has also been linked to changes in bladder function (De La Cruz et al., 2015). Attempts should be made to reduce or eliminate use of anticholinergics to the extent possible. Reductions in overall anticholinergic burden have been associated with improvements in behavioral and cognitive outcomes in affected elderly patients (Kersten et al., 2013). In cases in which these medications are used for a clinically indicated purpose, response should be closely monitored to determine if an appropriate effect is achieved, and the medication discontinued or changed if warranted.

A basic principle for prescribing medications in the geriatric patient population is to “start low and go slow.” This refers to the fact that lower medication dosages may be effective in older adults compared with younger patients and that high initial doses can often have adverse effects. Starting with lower doses and gradually increasing medication dosing with time can help to alleviate some of these potential problems. **One caveat that must be considered is that medication dose may have to be increased to reach the point of clinically efficacy.** Therefore care should be taken to avoid keeping doses of medications so low that they are not actually effective for symptoms they are prescribed to treat. Dose escalation should be continued until a clinically effective end point, maximum dosing for a particular medication, or intolerable side effects are reached.

It is also important for clinicians to avoid the "prescribing cascade." In these cases, a patient is prescribed a medication for a clinical problem. Because of side effects from this medication, they develop new symptoms that are attributed to a different cause, leading to prescription of a second medication to treat the side effects. To avoid this problem, clinicians should consider whether a new symptom may be due to a medication side effect rather than another cause. The AGS has included the concept that a medication review should be performed any time a new prescription is given as part of their "Choosing Wisely" list (AGS Choosing Wisely Workgroup, 2014).

Urinary Incontinence

The International Continence Society defines urinary incontinence (UI) as the involuntary loss of urine (Abrams et al., 2002). **From a clinical perspective, UI can be considered a specific diagnosis and a geriatric syndrome.** This is particularly true among frail older adults who may have multiple chronic conditions and geriatric syndromes (DuBeau et al., 2010; Fonda et al., 2005; Wagg et al., 2017). Urologists and gynecologists tend to view UI as a clinical diagnosis in contrast to geriatricians who conceptualize it more as a geriatric syndrome. As previously described, geriatric syndromes are defined as common conditions seen in older adults that are complex in nature, are usually multifactorial, and can have substantial clinical or other negative health outcomes for affected patients.

The incidence and prevalence of UI increase in older adults with more advanced age (Rohrmann et al., 2016)**. However, incontinence should not be considered a normal or inevitable part of the aging process.** Just because someone is elderly or frail does not mean that he or she should experience UI. This is a common myth among health care providers and patients that must be dispelled. **UI is more commonly associated with underlying medical conditions or other factors rather than chronologic age.**

Geriatric Specific Risk Factors for Urinary Incontinence

Several etiologic factors for UI and other forms of voiding dysfunction are unique to older adults and deserve special consideration**. Impairments in functional status, including dependence on others for ADLs, have been**

closely linked to increased prevalence of UI (Huang et al., 2007; Jenkins and Fultz, 2005; Khatutsky et al., 2013). Mobility impairment with diminished walking speed and balance may be important contributors to declines in ADL function and risk of UI (Fritel et al., 2013). Alterations in IADLs appear to have less influence on continence status compared with ADLs (Omli et al., 2013). Older adults are more likely to have multiple comorbidities that increase risk of developing UI. These include diabetes, metabolic syndrome, hypertension, and heart disease (Khatutsky et al., 2013; Smith et al., 2010). Risk factors for UI in elderly men and women can differ as a result of multiple factors, including anatomic differences, prior medical and surgical history, and lifestyle variables (Tikkinen et al., 2013).

Modifiable risk factors including smoking and alcohol use have been identified as risk factors for UI in geriatric cohort studies (Hirayama et al., 2009; Ikeda et al., 2011). Obesity and overweight are also linked to risk of UI in older adults. This may be due to increased intra-abdominal pressure and mobility impairments associated with morbid obesity. High body mass index (BMI) and increased waist circumference have been associated with UI in elderly patients (Byles et al., 2009; Krause et al., 2010).

Cognitive impairment, particularly after stroke or because of underlying dementia, presents a substantial risk for development of UI among older adults (Hatta et al., 2011). Among geriatric patients with dementia living at home, reported prevalence of UI ranges from 1% to 38%, and those with more severe symptoms require more specialized home care services (Drennan et al., 2013). Alzheimer dementia tends to be associated with loss of short-term memory, which can impair the ability of affected older adults to recognize sensations associated with a full bladder and need to void, accurately identify the toilet, and be able to adjust clothing or perform other tasks needed to maintain continence. Vascular dementia has been linked to diminished inhibitory control, which may influence continence status (Haruta et al., 2013).

Congestive heart failure (CHF) can cause UI for several reasons. Affected patients tend to make more atrial natriuretic peptide, which in turn leads to increased urine production. They also tend to have more problems with peripheral edema, which can increase urine output, particularly at night. **Increased CHF severity has been linked to increased UI severity in clinical studies** (Chiu et al., 2012; Palmer et al., 2009). More severe CHF is also associated with increased distress and increased use of absorbent pads and products to deal with the leaking (Meng et al., 2016). Diuretics are frequently used in management of CHF, and these can worsen UI because of increased urine output. Decreased pulmonary status with reductions in functional lung capacity have been associated with worse UI (Hirayama et al., 2009). Common neurologic disorders in older adults such as Parkinson disease can cause detrusor overactivity (DO) and associated urgency UI (Araki et al., 2000; Winge and Nielsen, 2012).

The term "aging in place" has been used to describe what is often considered an ideal paradigm in geriatrics. The goal is to help keep older adults living in their own homes as long as possible with as much independence as is feasible. Changes in ADL status including development of UI can be limiting factors in some cases. Older adults with UI and other ADL impairment may have greater needs for home health services compared with continent and more functionally independent elders (DuMoulin et al., 2009). Those living in residential care facilities have also been shown to have increased UI prevalence and care needs compared with community-dwelling older adults (DeGagne et al., 2013). In settings where public health resources are limited, older adults simply may not have access to these types of services (Burti et al., 2012).

Costs of Incontinence

The direct and indirect financial costs of UI are staggering. Medicare expenditure data showed that costs of care for UI nearly doubled from $128 million in 1992 to $234 million in 1998 (Anger et al., 2006). This represents a 15% per capita increase in treatment costs once adjusted for inflation. Other economic analysis has shown an estimated national cost of evaluation and care for overactive bladder with urgency UI of $65.9 billion in 2007 with projected increases to $76.2 billion in 2015 and $82.6 in 2020 (Coyne et al., 2014). This includes care for patients of all ages, not just older adults. Recent analysis has shown increasing rates of office visits, hospitalization, and other resource use for UI, which also tend to drive up associated costs (Thom et al., 2005). The estimated annualized cost in 2000 for nursing home admissions resulting from UI was $6.0 billion (Morrison and Levy, 2006). In addition, there are substantial environmental costs associated with use of absorbent pads and products going into landfills. Costs associated with care for OAB are particularly high among more vulnerable older adults with complex comorbidities. Recent estimates show an approximately $7000 increase per year in health care costs for these medically vulnerable geriatric patients with OAB (Chuang et al., 2018).

Negative Impacts of Urinary Incontinence

UI can have substantial negative health outcomes in older adults (Dugan et al., 2000). **The condition is associated with social isolation, depression, stigmatization, and embarrassment for many affected patients** (Lim et al., 2018). Many people discontinue activities that they enjoy because of urinary leakage. They may stop going out to the theater or movies, stop attending church or temple, or stop visiting friends because of the condition. Many people with UI feel a sense of embarrassment or shame, which can delay their choice to seek help for the condition (Vethanayagam et al., 2017). This has been shown to be true in multiple different cultures (Hamid et al., 2015). UI can lead to negative consequences, including physical, emotional, and financial costs for caregivers of affected individuals (Santini et al., 2016).

Incontinence can also have important negative physical effects. Chronic incontinence can be associated with skin irritation and breakdown, development or worsening of pressure ulcers, UTIs, and falls and fractures. UI also affects mental health, including increased rates of depression among affected older adults (Laganà et al., 2014). Research has shown that **UI has a stronger negative influence on overall levels of happiness than many other common chronic conditions in older adults, including diabetes, hypertension, arthritis, and osteoporosis among others** (Angner et al., 2009). Only chronic debilitating pain has been shown to be a stronger negative predictor of diminished happiness.

UI can have a substantial negative effects on general and health-related quality of life (HRQoL) in older adults. It limits the ability of people to participate in leisure activities and engage with others in the community (Kwong et al., 2010). Many older adults stop participating in activities they enjoy because of fear or embarrassment about urinary leakage. The associated psychosocial effects can be substantial and include problems with depression and social isolation (Chung RY et al., 2013; Lee YI et al., 2013; Pintarelli et al., 2011; Sahin-Onat et al., 2014; Yip et al., 2013). Depression can be particularly problematic among older adults and can cause issues in other facets of life, including mental health domains, nutrition and eating, sleep quality, and happiness (Angner et al., 2009; Sexton et al., 2011).

UI can cause significant psychological distress for elderly patients, often because of their reduction in other activities (deVries et al., 2012). Many older adults require assistance with toileting and other ADLs. Levels of caregiver burden can also be substantially higher among those with associated UI, particularly if other ADL impairments are present (Gotoh et al., 2009; Miu et al., 2010; Tamanini et al., 2011). The type of UI may influence outcomes related to quality of life, particularly for those with mixed symptoms (Frick et al., 2009). However, other epidemiologic studies in older adults have shown the degree of incontinence as measured by severity appears to be more influential on HRQoL outcomes compared with type of UI (Aguilar-Navarro et al., 2012; Barentsen et al., 2012).

Among those older adults living in nursing homes, UI has been shown to have negative impacts on a number of important quality-of-life parameters, including dignity, autonomy, and mood (Xu and Kane, 2013). Successful treatment of UI has been shown to substantially improve HRQoL outcomes (Fonda et al., 1995).

Established Versus Transient Incontinence

Established Urinary Incontinence.

Established or chronic UI is an extremely common problem seen in geriatric patients. Recent epidemiologic data show that of all people over 65 years of age, 43.8% report a history of any urinary leakage (Gorina et al., 2014). Among community-dwelling elderly women, 12% report severe or very severe UI. More than half of community-dwelling women and about a quarter of men report experiencing UI. Overall, 36.6% of those in residential care facilities, not including nursing homes, experienced UI, and women were 1.2 times as likely to report this than men (95% CI 1.03–1.4). Similarly, of those older adults receiving home care services, 40.2% reported problems with bladder control, and women were 1.7 times more likely to experience this compared with men (95% CI 1.3–2.1) (Gorina et al., 2014).

Transient Versus Established Urinary Incontinence.

Urinary incontinence in older adults is frequently transient. In fact, studies indicate that **up to 30% of UI in community-dwelling older adults and nearly 50% of UI in elderly patients admitted to acute care hospitals may be caused by transient conditions** (Herzog and Fultz, 1990; Resnick et al., 1988). The identification of transient incontinence among elderly patients is important because it highlights the interplay between various organ systems and genitourinary function. For example, if a patient develops worsening peripheral edema because of an exacerbation of CHF, this could increase nocturnal urinary production and associated nocturia or nocturnal enuresis. Similarly, temporary mobility impairment from lower extremity cellulitis in a patient with DO and urinary urgency may lead to development of urgency UI. Although no direct changes occurred in bladder function in either example, changes in fluid volume or mobility status led to urinary leakage. Treatment of underlying causative conditions could result in improvement or complete resolution of UI. Prospective evaluation and treatment for these conditions in elderly patients has been shown to be effective (Resnick, 1989).

A wide variety of conditions can lead to associated transient UI. Patients with sudden or new onset of UI symptoms should be screened for possible associated causative conditions. However, even patients with longstanding urinary incontinence can suffer if these underlying conditions have been present but untreated over time. Multiple causes are frequently involved in geriatric patients.

Transient Urinary Incontinence.

UTI causes an inflammatory reaction in the urothelium, which can lead to increased sensations of bladder filling. This causes urinary frequency and, in some cases, UI. This should be considered symptomatic and evaluated and treated appropriately. In contrast, true asymptomatic bacteriuria does not by itself cause UI and does not require antibiotic therapy. Atrophic vaginitis or urethritis is common in elderly women and may be associated with dysuria or a burning sensation with voiding. Physical examination reveals thinning and loss of rugation of vaginal mucosa, although inflammatory changes with erythema and mucosal hemorrhage may also be seen in a minority of patients. In elderly women who are sexually active, atrophic vaginitis can lead to dyspareunia. Treatment with vaginal estrogens can help ameliorate symptoms of this condition and may help improve continence status in affected individuals. It also helps reduce incidence of symptomatic UTIs in postmenopausal women (Goldstein et al., 2013).

Fecal impaction is frequently seen in older adults. This can be caused by slow transit time through the gut or increased water reuptake in the colon. Fecal incontinence and diarrhea may be presenting symptoms because liquid stool proximal to the impaction moves around the impacted stool bolus. Disimpaction often results in resolution of urinary and fecal symptoms. Chronic constipation is a common problem in older adults. Treatment and prevention with a bowel regimen can help. This typically involves multiple modalities including stool softeners, increase in dietary or supplemental fiber, increased fluid intake, and judicious use of products such as polyethylene glycol (Miralax) (Schnelle et al.,

2010).

Numerous different medications can cause transient incontinence in older adults including psychotropics, diuretics, benzodiazepines, angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers, tricyclic antidepressants, methylxanthines, alpha-blockers, and narcotic analgesics among others (Kashyap et al., 2013; Landi et al., 2002; Tsakiris et al., 2008). Polypharmacy is a common problem in older adults, which has also been linked to increased risk of UI (Talasz and Lechleitner, 2012). Diuretics are commonly prescribed for treatment of hypertension or peripheral edema but cause an increase in urinary production that can overwhelm the bladder and cause urinary urgency, frequency, and urgency UI (Peron et al., 2012). If taken at night, diuretics can potentially induce nocturia and nocturnal enuresis. The ACE inhibitors, also used to treat hypertension, can induce cough and worsen stress UI, particularly in older women. Combinations of these medications for treatment of hypertension have been shown to have synergistic effects in worsening UI in older adults (Peron et al., 2012). Opioids and narcotic analgesics tend to decrease detrusor contractility and can cause urinary retention with associated incontinence. Cholinesterase inhibitors prescribed to help slow progression of memory loss in Alzheimer dementia can increase detrusor contractility, leading to symptomatic UI (Hashimoto et al., 2000). Tricyclic antidepressants can exert a strong anticholinergic effect and decrease detrusor contractility leading to difficulty voiding or urinary retention. The alpha-adrenergic receptor antagonists cause smooth muscle relaxation and can worsen stress urinary incontinence, particularly in women.

Data from the Women's Health Initiative Study demonstrated that systemic administration of estrogen was actually associated with increased rates of UI (Hendrix et al., 2005). It is one reason that systemic estrogen is usually not encouraged in elderly women. The most recent update of the AGS Beers criteria also includes a recommendation to avoid systemic estrogens in elderly women because of this increased risk of UI (American Geriatrics Society Beers Criteria Update Expert Panel, 2012). Alcohol and other substance abuse should also be considered as potential causes of UI. Anticholinergic medications can worsen UI by exacerbating urinary retention and incomplete bladder emptying. This in turn can lead to more urinary frequency as the bladder reaches capacity quickly even after voiding. In addition, older adults may have decreased salivary secretions, which can be worsened by anticholinergic medications. Increased fluid intake in response to this dry mouth can worsen incontinence symptoms. Over-the-counter decongestant medications used to treat colds and flu often have strong anticholinergic properties. These can worsen urinary retention, particularly in men with underlying BPH and some degree of BOO.

Psychological or behavioral factors including depression or anxiety can lead to changes in continence status (Steers and Lee, 2001). Successful treatment of underlying psychological issues may help reduce or resolve UI. Similarly, delirium or dementia can cause incontinence resulting from cognitive changes. In delirium, these are typically associated with acute confusion and fluctuation in status and inattention. Dementia tends to be more longstanding and progressive over time but can also be associated with substantial cognitive change and inattention to voiding (Lee et al., 2014). Although dementia may not be reversible, acute delirium is typically treatable and UI may resolve with abatement of acute cognitive changes.

Mobility impairment can cause problems with UI (Kim et al., 2015). This can be due to either acute or chronic conditions. Hip and long bone fractures, arthritis, joint deformities, spinal stenosis, and claudication can significantly limit mobility. Other gait and balance problems include disequilibrium, vertigo, orthostatic or other forms of hypotension, generalized deconditioning, and muscle weakness. Visual impairment and other sensory limitations can increase fear of falling and result in reduction of mobility. Stroke often leads to mobility impairment, which may or may not improve with time and rehabilitation. Normal pressure hydrocephalus is a condition seen more commonly in older adults. The condition is characterized by a triad of symptoms, including ataxic gait, cognitive dysfunction, and urinary incontinence. Ventriculoperitoneal (VP) shunt placement is the main therapy for NPH and may lead to complete resolution of symptoms, particularly if patients are treated relatively early after onset of symptoms (Akiguchi et al., 2008). Other neurologic disorders can lead to problems with UI in elderly patients. Parkinson disease is often associated with sleep disorders and may increase nocturia (Vaughan et al., 2013). It also increases risk of urinary urgency and DO. UI is particularly common in older adults with Alzheimer disease, Lewy body dementia, and vascular dementia (Ransmayr et al., 2008; Sakakibara et al., 2005). A recent epidemiologic study showed a 6.2% incidence rate for UI in patients with underlying Alzheimer disease (Lee et al., 2017). Involvement of the frontal lobe(s) of the brain appears to be particularly important in the association between Alzheimer disease and UI (Sugimoto et al., 2017).

Excess urinary output, polyuria, can also lead to transient UI. In addition to diuretics, other potential causes include metabolic derangements, CHF, pulmonary edema, venous insufficiency, malnutrition with hypoalbuminemia, diabetes insipidus, a syndrome of inappropriate antidiuretic hormone (SIADH) production, or excessive fluid intake resulting from psychogenic polydipsia or other factors. Peripheral edema can cause increased urine production when the patient moves to a recumbent position and tissue fluid recirculates leading to increased urinary production. Affected patients may benefit from elevating their legs above heart level late in the afternoon to offload some of this excess fluid before retiring to bed, thus reducing nocturia. Numerous medications can also exacerbate the development of peripheral edema including thiazolidinediones or glitazone medications used to treat diabetes, amantadine used to treat Parkinson disease, beta-blockers, calcium channel blockers, or nonsteroidal anti-inflammatory drugs (NSAIDs).

Types of Established Urinary Incontinence.

The major categories of established UI in older adults are similar to those in younger people, although some important clinical caveats must be noted (Diokno, 1990).

Urgency UI is the most common form of established incontinence among elderly people. This is typically associated with symptoms of urinary urgency and frequency. DO is often seen on urodynamic evaluation and is a common cause among older adults (Griebling, 2013b). The International Continence Society (ICS) defines urgency incontinence as the complaint of involuntary leakage accompanied by or immediately preceded by urgency, and DO as a urodynamic observation characterized by involuntary detrusor contractions during the filling phase that may be spontaneous or provoked (Abrams et al., 2002). Although the exact cause of DO is unclear, a number of different theories and mechanisms associated with aging have been explored. These include bladder and pelvic organ ischemia, free radical release and tissue damage from oxidative stress, inflammatory effects, changes in central and peripheral neural control, and cellular dysfunction (Chancellor, 2014; Smith, 2010; Tyagi et al., 2014a; Young et al., 2013).

Normal urine storage and voiding is a complex process that requires synchronous interaction between the bladder and peripheral and central nervous systems. Interaction between brain activity and bladder function in older adults has been the subject of recent research interest (Griffiths et al., 2005, 2007). Studies have used static and functional magnetic resonance imaging (MRI), sometimes done in conjunction with urodynamics, to assess these relationships (Krhut et al., 2012; Morris, 2013; Tadic et al., 2012). Normative data examining continent younger and elderly women have been obtained using functional MRI scanning during bladder filling and voiding (Griffiths et al., 2009). This includes data on motor and sensory changes in control patients associated with small filling volumes often associated with urgency in symptomatic patients (Tadic et al., 2013). In contrast to asymptomatic controls, patients with a history of urinary urgency, frequency, and UI tend to have an increase in white matter hyperintensities on brain MRI (Kuchel et al., 2009; Wehrberger et al., 2013). These findings support the hypothesis that alterations in brain anatomy and physiology may play a crucial role in urinary control in older adults. Additional research will help to further elucidate these complex processes and may identify future targets for therapy.

UI is particularly common after stroke. **Approximately 70% of stroke survivors experience problems with bladder control** (Marinkovic and Badlani, 2001). **Stroke severity is closely linked with development of UI, and those with more severe strokes tend to have more severe incontinence problems** (Panfili et al., 2017). Ischemic and hemorrhagic stroke can cause subsequent incontinence. Continued UI in those who were previously dry is a marker condition for increased morbidity and mortality after stroke (Patel et al., 2001). Stroke laterality and hemispheric dominance have generally not been found to be associated with differences in UI patterns or severity (Gupta et al., 2009; Kim et al., 2010). However, brainstem strokes that affect the pontine micturition center tend to cause worse incontinence. DO is the predominant urodynamic finding in patients with post-stroke incontinence and is typically associated with urinary urgency, frequency, and urgency UI. However, some patients experience poor detrusor contractions and chronic urinary retention with associated incontinence. Continued UI after stroke is associated with greater levels of functional dependence and higher overall care needs (Mizrahi et al., 2011). Post-stroke incontinence has been linked to poorer overall quality of life and alterations in sense of well-being (Tibaek et al., 2011). Fecal incontinence is also a common finding in patients with post-stroke UI resulting from overlap in neural control mechanisms (Brittain et al., 2006; Kovindha et al., 2009). Interaction between cognitive and mobility impairment after stroke and associated UI and voiding dysfunction is complex. Among those with mobility impairment, decreased mobility velocity has been linked to worse LUTS severity (Tibaek et al., 2009).

The term *precipitancy* has been used to describe the symptom that occurs with DO in older adults (Resnick, 1990). In patients with no sensation of warning, precipitant leakage may be experienced as an unconscious or reflex episode of incontinence. In contrast, in those with a warning sensation, precipitancy is the abrupt sensation of imminent leakage, regardless of time interval or the amount of urine loss (Resnick, 1990).

DO may exist in with or without other comorbid disease. **Underlying neurologic disorders such as Parkinson disease, Alzheimer disease, multiple sclerosis, spinal stenosis, or prior stroke tend to be associated with DO and related urinary dysfunction.** Sometimes bladder symptoms are among the earliest signs of some conditions such as multiple sclerosis (Chesnel et al., 2018). However, in many cases, no specific cause for DO can be identified. This makes evaluation and targeted treatment of DO in older adults more challenging.

The term *OAB* is used to describe the symptom complex experienced by patients. This includes “urgency, with or without urge incontinence, usually with frequency and nocturia” (Wein and Rovner, 2002). This can be further subdivided into OAB-dry, in which patients experience urinary urgency and frequency symptoms but do not actually leak urine, and OAB-wet, in which urgency UI also occurs. Older adults often develop specific coping mechanisms to deal with their symptoms of OAB, including voiding on a schedule or identifying and mapping where toilets are when they go out of their home (Blasco et al., 2017).

One form of bladder dysfunction that is unique in the geriatric population is detrusor hyperactivity with impaired contractility (DHIC) (Resnick and Yalla, 1987). In this condition, the patient experiences DO with bladder filling, which is associated with the typical symptoms of urinary urgency, frequency, and potentially with urgency UI. However, during the voiding effort, the bladder does not contract efficiently or with sufficient force to completely empty. In some ways, this represents a functional combination of overactive and underactive bladder. Brain imaging studies have shown hypoperfusion abnormalities that localize to the frontal and global cortical areas and are often associated with cognitive impairment (Griffiths et al., 2002). In some cases, detrusor contraction strength may actually be increased, particularly in presence of urgency UI. Monotherapy with antimuscarinic medications or other bladder relaxants can worsen urinary retention and promote development of chronic urinary retention with associated incontinence. Successful treatment often requires multimodal therapy including behavioral interventions and medications to inhibit DO and clean intermittent catheterization (CIC) to empty the bladder. Intentional induction of urinary retention with antimuscarinic medications to control hyperactivity, combined with CIC performed on a regular schedule to empty the bladder, can be a successful method for clinical management in some patients. Future research will be needed to help develop more optimal forms of management for this complex condition (Smith et al., 2014; Taylor and Kuchel, 2006).

Stress urinary incontinence (SUI) is common in older people and may occur in men and women. **In women, stress UI is usually due to either urethral hypermobility or intrinsic sphincter deficiency.** Pelvic floor support and urethral closure pressure tend to decrease with advancing age, and this increases risk of urethral hypermobility and intrinsic sphincter deficiency (ISD) in elderly women. Urethral atrophy associated with decreased tissue estrogenization, and other age-related factors can exacerbate ISD and stress UI in this population. Stress UI in men is often related to prior surgical therapy for either BPH or prostate cancer. Transurethral resection of the prostate (TURP) and radical prostatectomy have been associated with increased risk of stress UI in men. Enhancements in surgical technique and targeted therapy with pelvic floor muscle exercise (PFME) and other behavioral interventions may potentially reduce overall incidence and prevalence of postprostatectomy UI in older men (Goode et al., 2011; Kojima et al., 2013; Mirza et al., 2011).

Detrusor underactivity, sometimes called “underactive bladder” can be caused by a wide variety of conditions. Often the cause is idiopathic, but recent research has led to emerging data on this condition (Chancellor, 2014; Griebling, 2013a; Griebling et al., 2014b). Poorly controlled diabetes can lead to impairment of bladder contractility and a “diabetic cystopathy.” Patients can develop impairments in bladder sensation leading to behavioral changes and a prolongation of the intervoiding interval. This cyclic but chronic bladder overdistention may be associated with subclinical bladder ischemia, which leads to progressive muscle dysfunction. Pelvic atherosclerosis is associated with diminished arterial blood flow to the bladder, which could cause ischemic changes. This in turn can promote development and release of free radicals and accumulation of oxidative stress causing damage to cells and tissues.

Untreated chronic BOO can lead to detrusor dysfunction and chronic urinary retention in men, although this is less common with early detection and targeted interventions. Anatomic urethral obstruction in women is uncommon and most typically caused by prior urethral trauma. Large POP can cause functional obstruction with urethral kinking or angulation. Many of these women describe having to manually reduce prolapse with a finger in the vagina to void to completion. Use of a pessary or surgical prolapse repair can help treat this type of voiding dysfunction. Iatrogenic urinary retention can occur after surgical therapy for stress UI and may require surgical revision of the prior repair (Anger et al., 2007a, 2007b).

The term *functional incontinence* is sometimes used to describe urinary leakage caused primarily by factors other than the bladder. The ICS does not specifically define or recognize this term, but it is commonly used in research and clinical practice. **The most common factors associated with functional incontinence in geriatric patients include mobility limitations and cognitive impairments.** Care must be exercised to consider potentially reversible causes of transient UI other than restricted mobility and cognitive changes because these can coexist in patients thought to have functional incontinence. The identification of a functional component should also not presume that underlying lower urinary tract function is normal. Indeed, older adults with mobility or cognitive impairment and functional incontinence may have other underlying urologic pathology that predisposes them to UI. **Neither cognitive impairment nor immobility mean that UI will be an inevitable outcome. In fact, the majority of older adults with mobility limitation and cognitive impairments are actually continent.** In one study of nursing home residents, 17% with severe dementia were continent, and if they were able to transfer between the bed and a chair, half were continent (Resnick et al., 1988). It is also important to consider these functional limitations because, although they may not directly cause UI, they can certainly contribute to the condition in otherwise susceptible individuals. Even multiple small improvements in various functional components can substantially improve or resolve UI and associated clinical problems.

Incontinence in the Nursing Home Setting

UI is one of the most common conditions found in older adults living in nursing homes and other long-term care settings. Based on national data, reported prevalence of bladder incontinence is 46.1% for short-term nursing home residents and 75.8% for long-term care residents (Gorina et al., 2014). Similar rates have been observed in other countries with more than 50% of nursing home residents experiencing chronic incontinence (Jerez-Roig et al., 2016). UI is often considered one of the primary factors that necessitates facility placement among older adults. Using national data, the calculated attributable fraction of nursing home admissions resulting from UI is approximately 0.10 (95% CI 0.08–0.13) for men and 0.06 (95% CI 0.05–0.09) for women (Morrison and Levy, 2006; Thom et al., 1997). However, **new onset of UI is also a common finding among nursing home residents after admission to care facilities** (Ouslander et al., 1993; Palmer et al., 1991). Efforts have helped to substantially reduce use of indwelling urinary catheters in nursing homes, and most facilities now report relatively low rates of 7.3% among long-term residents, and 13.9% in short-term residents (Gorina et al., 2014). Short-term urinary catheters can be useful, particularly in older adults with associated clinical problems such as mobility limitation from lower extremity or pelvic fractures. However, even in these circumstances, rates of catheter associated infections of more than 30% have been reported (Kamdar et al., 2009).

Efforts to decrease rates of catheter-associated urinary tract infections (CAUTIs) have taken priority in acute care settings and nursing homes (Averch et al., 2015). This includes application of standard definitions to establish the diagnosis (Armbruster et al., 2017). Enhanced awareness of the appropriate indicates and uses for catheters can help with this (Hu et al., 2015). Reduction in CAUTIs has been associated with decreased overall costs of care (Hutton et al., 2018).

All nursing home residents undergo a comprehensive evaluation, including an assessment of urinary control and continence status, at the time of admission. Additional assessments are performed at least quarterly and more frequently if clinically indicated. Completion of the Minimum Data Set (MDS), a comprehensive multidimensional clinical assessment and documentation tool, is required for every nursing home resident in facilities that receive reimbursement from Medicare and/or Medicaid. It is completed within the first 2 weeks of admission, and at least annually. A short form is completed quarterly and in cases of substantial clinical change. Nursing homes in the United States are under strict regulatory control, and frequent inspections are required. F-Tag 315 is the national quality measure that examines UI and catheter use in nursing homes (Johnson and Ouslander, 2006). It is used to help facility surveyors assess care for UI and catheter use in long-term care facilities. In a survey study of nursing home staff and state surveyors there were substantial differences in knowledge about UI and attitudes toward this federal regulation (DuBeau et al., 2007). Other research has shown similar variation in levels of understanding and attitudes about UI by nursing home staff (Saxer et al., 2009). **Organizational**

factors can be as important as clinical medicine and nursing issues in this setting (Yoon et al., 2012). This highlights the need to include nursing home staff and administrators in quality improvement. Process change in nursing home settings can be challenging, and ongoing research seeks to improve these methods (Grabowski et al., 2014).

Catheters are generally not used for UI management in this setting. Rather, they are used for treatment of chronic urinary retention, particularly among older adults who would not otherwise tolerate clean intermittent catheterization (CIC) because of physical or cognitive issues or in cases of significant caregiver burden (Jonsson et al., 2011b; Lin et al., 2011). **Continued use of indwelling catheters in nursing home residents is subject to intense scrutiny and must be clinically justified in each specific case** (Gammack, 2003). Management of UI and other voiding dysfunction among morbidly obese nursing home residents can be particularly problematic. These individuals often suffer from multiple comorbid conditions, and mobility and transfers may be severely limited (Bradway et al., 2010). Catheter use may be considered in select cases.

The need for continued Foley catheter drainage among older adults discharged from acute care hospitalization has been associated with substantially increased rates of short-term mortality and need for institutional placement at time of discharge (Bootsma et al., 2013). However, caution must be used to balance risk and benefit. Bacterial colonization is common with 98% of indwelling catheters among geriatric nursing home residents affected (Jonsson et al., 2011a).

Absorbent pads and products are often used as part of a “check and change” approach to management of UI in geriatric nursing home residents, particularly in cases in which more active forms of therapy may not be feasible because of cognitive or other functional impairments. Although many nursing home residents prefer scheduled toileting and active interventions, use of pads and products can be effective in select cases (Pfisterer et al., 2007). Research has shown, however, that pad-per-day usage does not necessarily correlate well with actual UI volumes or severity (Omli et al., 2010).

Urologic consultation in nursing home settings can be useful for evaluation and management of complex genitourinary conditions, or to supplement ongoing therapies administered by nursing home staff (Watson et al., 2010). This can obviate the need to transport older adults from their place of residence to outpatient clinics or hospital settings. However, in the current national model of physician reimbursement, this type of onsite consultation service can be difficult to maintain over time because of administrative and cost barriers.

Targeted protocols to treat UI in long-term care settings have proved successful. Prompted toileting can be used with residents who have adequate mobility and cognitive function to use toilet facilities independently. Patients are prompted by caregivers or staff to use the toilet on a regular schedule. Timing is adjusted based on specific individual needs. In those older adults with mobility and/or cognitive impairment, assisted toileting procedures may be necessary. These involve having staff physically assist older adults to the toilet and guiding them through the process of adjusting clothing, using the toilet, and cleaning after voiding and/or defecation. Individually devised plans may be needed for each resident depending on his or her condition. Use of bladder scan ultrasound may be useful in this process to help identify when subjects need to use the toilet (Iwatsubo et al., 2014). This has been successfully combined with prompted toileting programs (Suzuki et al., 2016). The use of assistive toileting devices such as handheld urinals or bedside commodes may be necessary depending on functional status. Functional incidental training (FIT) has been used as a successful model of assisted toileting with older nursing home residents. In the FIT model, residents combine physical activity and mobility training with scheduled and assisted toileting (Schnelle et al., 1995).

Clinical Evaluation of Incontinence.

Clinical evaluation of UI in older adults requires special consideration of associated health factors and can differ substantially from standard evaluation in younger and healthier patients. In particular, **careful attention must be paid to potential contributions of comorbidity, either as a causative factor or an effect from UI.** Evaluation should seek to identify any of the previously described reversible transient causes of incontinence. It should also assess caregiver and social support, and the environmental setting where the older adult resides. The evaluation could also identify other serious urologic conditions that can be associated with UI including bladder cancer, benign or malignant prostate disease, neurologic disorders, or stone disease.

Evaluation should be individually tailored to the clinical needs and goals of the patient and his or her caregivers. In some cases, complete resolution of UI may not be feasible, but even small improvements in the condition can yield substantial functional results. For example, improvement in volume or frequency of urinary leaking may allow someone who was previously confined to the home the ability to get out and interact in social settings more easily.

Simple interventions can sometime have substantial positive effects. In most clinical guidelines, these form the cornerstone of initial therapies. However, a comprehensive approach is often the most effective when addressing the complex topic of UI in older adults.

History.

A detailed history is essential to proper diagnosis and selection of therapy for UI in older adults. The characteristics of incontinence, including duration, frequency and volume, should be determined. Any exacerbating factors such as physical activity, coughing, laughing, sneezing, or other factors should be assessed. A review of medical records can be extremely valuable. This would include any prior treatments that have been attempted, and prior surgical records if available. Some patients will be unable to provide their own historical information, and portions of, or in some cases the entire, history may have to be obtained from caregivers or surrogates. A telephone call to the patient's geriatrician or primary care provider can be valuable for obtaining historical information. For those older adults who reside in long-term care facilities, a call to the nursing staff member most familiar with them can help put clinical questions into better context. This can also help clarify goals of evaluation and treatment.

In some cases, a careful history will allow the clinician to determine the type(s) of UI a given patient experiences. However, this is not always true, particularly for elderly patients who may have more complex voiding dysfunction. The symptom of urinary urgency is extremely common but is neither particularly sensitive nor specific for DO. This may or may not be accompanied by actual urinary leakage. Similarly, urinary frequency is a common complaint that must be placed in clinical context. This may be caused by true DO, sensory changes that results in frequency of urination, or incomplete urination leading to rapid refilling of the bladder. In some cases this is a learned behavior or purposeful technique to avoid UI that may occur near bladder capacity. Voiding diaries can be helpful in gaining more insight into these clinical complaints.

Identifying the most bothersome component or characteristics of UI is particularly important in older adults. This can help to target treatments that can yield clinically meaningful improvements even if urinary leakage cannot be completely eliminated and is one of the main components of patient-centered therapy.

Physical Examination.

The physical examination is a crucial part of overall assessment of older adults with UI. In addition to routine aspects of physical examination including pelvic examination in women and genital and rectal examination in men, several unique components are also included for older adults with incontinence. The general physical examination should include identification of conditions associated with fluid overload and associated incontinence including peripheral edema, congestive heart failure, and pulmonary edema.

Neurologic examination includes gait and balance, mobility, and ability to transfer between positions. This includes ability to get on and off a chair, which can be similar to getting on and off the toilet. Clinical signs associated with common rheumatologic and neurologic disorders in older adults should also be evaluated. These include changes from arthritis and joint disorders, Parkinson disease, multiple sclerosis, prior stroke, spinal stenosis, cord compression, vertebral disc herniation, acute or chronic back pain, dementia, and delirium.

Perineal sensation should be tested and may be diminished or asymmetric, particularly in those with a history of underlying neurologic disease. For example, patients with a history of stroke and associated hemiparesis may have asymmetric perineal sensation. Tissue quality should be assessed, including presence or lack of rugation of the vaginal mucosa. Atrophic vaginitis is common in postmenopausal women and is usually due to lack of estrogen. This can also lead to fusion or agglutination of the labia minora or labia majora. In some cases this can cause voiding dysfunction and BOO (Chang et al., 2012). Vaginal narrowing or stenosis is another common finding on pelvic examination in elderly women. This is sometimes associated with a prior history of pelvic radiation therapy.

Pelvic examination in women should be performed with the bladder moderately full to evaluate for stress UI. Many older women wish to void before pelvic examination because it makes this more comfortable, and they may be used to doing so before routine gynecologic examinations. In some cases, women want to void before examination to avoid potential embarrassment with urine leakage in front of the clinician. However, if the patient voids to completion before the examination, determination of stress leakage with cough or Valsalva will be severely limited. Gentle reassurance of the importance of doing the examination with urine in the bladder and objective identification of stress leakage can be very useful and can help put the patient at ease.

Rectal examination may reveal signs associated with chronic constipation or fecal impaction. The bulbocavernosus reflex may be absent in older adults, although this change may or may not be associated with underling neurologic pathology. Prostate enlargement or nodularity may be palpable, although prostate size on rectal examination does not necessarily correlate with symptoms. Rectal cancers are more common among older adults, and the majority of lesions are palpable on digital rectal examination. Stool guaiac testing should also be considered and can help to identify otherwise silent pathology in some patients (Goetzl et al., 2008).

Having the patient void as part of the physical examination can be particularly useful in geriatric patients. This may include actually taking the patients to the toilet to observe their behaviors and level of need for assistance. Are patients able to recognize the toilet? Are they able to identify the sensations provided by a full bladder and respond appropriately to these signals? Are they able to adjust their clothing independently to allow use of the toilet? This can provide insight into potential issues of cognitive or physical functional impairment that could change the course of recommended therapy.

Assessment of Postvoid Residual Volume.

Many older adults do not completely empty the bladder with voiding. **Elevation of the postvoid residual (PVR) is common in older adults. However, no specific volume is considered pathological, and there is a great deal of controversy surrounding the importance of elevated PVR in older adult patients** (Huang et al., 2011; Shimoni et al., 2015).

Measurement of PVR can be accomplished with either ultrasound scan or bladder catheterization. Ultrasound is convenient and eliminates the need for urethral instrumentation. However, the device is expensive, and not all clinics will have this equipment available. Some nursing homes, outpatient clinics, emergency rooms, and other facilities that provide care for older adults have invested in this type of technology (Omli et al., 2008).

Measurement should ideally be completed immediately after a voluntary void rather than after an incontinent episode. However, in some patients, particularly those with cognitive impairment, this may not be feasible. Measurement of PVR after an incontinent leakage episode can be useful, particularly if the volume is low because this indicates complete bladder evacuation.

Voiding Diaries.

The use of voiding diaries can be particularly helpful in assessing UI and other forms of voiding dysfunction in older adults. They can help identify patterns of voiding in terms of time and associated factors. This can be useful to differentiate the type of UI in some cases. It can also be helpful in identifying cases of daytime or nocturnal polyuria. Research has shown diaries completed over 3 days can be valid for analysis, and this eliminates need for extended 7-day or longer diaries (Dmochowski et al., 2005). Most diaries are completed using paper forms, although electronic diaries are also available and are frequently employed in clinical research trials. If clinicians are going to use voiding diaries with older adult patients, care should be used to make sure the font is large and easily readable and that adequate instructions are provided for proper completion.

Findings from the voiding diary can be very useful in helping to guide treatment for UI in older adults. The voiding diary can help identify voiding patterns and provides an objective tool to validate subjective symptoms. It can be particularly helpful in patients with nocturia to differentiate nocturnal polyuria from some of other causes of the condition (Udo et al., 2009; Weiss and Blaivas, 2000). In some cases, recording fluid intake may be useful, but this increases the complexity of data the older adult is asked to complete. Information on fluid intake is particularly useful to identify polydipsia or fluid restriction, which could be causing voiding problems.

Laboratory Testing.

Geriatric patients need some special considerations for laboratory testing related to urologic health. Urinalysis and urine cultures should be obtained when clinically indicated and can help to identify underlying comorbidity. **The American Urological Association (AUA) Guidelines recommend checking a urinalysis as part of the initial evaluation for UI** (Dmochowski et al., 2010; Gormley et al., 2012). Gross or persistent microhematuria warrants additional evaluation, including in those older adults who are on anticoagulation therapy (Davis et al., 2012). Urine cultures are important to help diagnose the cause of UTIs and guide therapeutic choices. Persistent sterile pyuria should raise suspicion for possible genitourinary tuberculosis in older adults who can harbor this infection without other signs or symptoms (Kulchavenya et al., 2013).

Measurement of serum creatinine alone frequently does not adequately reflect true renal function in geriatric patients. This is due to natural loss of muscle mass with aging, which influences observed serum creatinine levels. Several options have been developed to correct for this measurement disparity

(Aucella et al., 2010). A 24-hour urine collection will provide the most accurate information but may be difficult to obtain for many patients, particularly those with substantial UI. The most commonly used estimation equations include the Cockcroft-Gault and Modification of Diet in Renal Disease (MDRD) models. Correction factors for age and body habitus can help improve accuracy of these estimates of glomerular filtration rate (Schaeffner et al., 2012; Van Pottelbergh et al., 2014; Zhu et al., 2014).

Serum electrolytes should be checked in patients with delirium because this can be a causative and potentially reversible factor in some cases. Glucose measurement is useful in diagnosing underlying diabetes that could be associated with renal, lower urinary tract, and sexual health disorders.

Urodynamics.

Urodynamics can be useful in the evaluation of select elderly patients with urinary incontinence and other forms of voiding dysfunction (Diokno, 1990). The AUA recently published guidelines regarding the use of urodynamics for assessment of voiding dysfunction (Winters et al., 2012). **Primary indications for urodynamics, particularly in older adults, include failed prior therapy, underlying neurologic or other comorbid conditions that could influence voiding function, and planned genitourinary reconstruction.** It is important to consider if and how findings from urodynamic testing may change treatments. If different urodynamic results would not alter therapy, then testing would not be warranted. However, if different treatment options would be considered based on the observed results from the testing, then it would be justified. Pressure-flow urodynamics can be particularly helpful to differentiate between functional obstruction and underactive bladder with poor contractility and incomplete bladder emptying.

Several factors must be specifically considered for geriatric patients who may undergo urodynamic testing. Although minimally invasive, the study is in some ways an interventional procedure and must be conducted in this context. The test is interactive, and patients need to be able to follow directions and describe what they are feeling at various points. They need to be able to be positioned adequately and undergo catheter placement. Older adults with cognitive or mobility limitations may have difficulty participating in urodynamic testing, which could compromise the quality of the findings. **Ideally, the symptoms being targeted for analysis and treatment should be reproduced during urodynamic testing.** This can be difficult to achieve in the urodynamic laboratory, but a variety of techniques can be employed to help with standardization of methodology. The importance of good urodynamic technique and testing quality cannot be overemphasized (Schäfer et al., 2002). Most urodynamic testing is conducted in hospital- or clinic-based facilities, although portable and ambulatory urodynamic evaluation can be performed in select cases. The role of urodynamic testing in the nursing home and other care settings is relatively limited and should be reserved for specific cases in which results of the testing would substantially influence treatment considerations. Staffing and reimbursement may also be a limiting factor for studies done in mobile settings such as nursing homes.

In a large cohort study of urodynamic findings in 100 community-dwelling elderly women, the most common clinical conditions identified include DO and DHIC (Valentini et al., 2010). These tended to be strongly correlated with patient symptoms. However, other studies have contradicted this finding and suggest that in some older adults the observed correlation between clinical symptoms and urodynamic findings may be lower (Bromage et al., 2010). This likely reflects alterations in anatomy or physiology and overall heterogeneity of changes seen with advancing age among older adults.

Treatment of Incontinence.

Treatments of UI must be carefully tailored to the individual patient. This is particularly true among geriatric patients in whom there can be substantial heterogeneity between individuals based on comorbidities, functional status, and goals of care. Because causes of established UI in geriatric patients are multifactorial, treatment also frequently requires multiple components and approaches. **In many cases, the actual target of therapy may be outside of the lower urinary tract to address contributions from comorbidities and other contributing clinical conditions.** Behavioral therapies are a mainstay of treatment of UI in geriatrics, although medications and surgeries can also be used successfully in this population.

Behavioral Therapies.

Behavioral therapies are considered the mainstay of therapy for treatment of UI in older adults. They offer the advantage of good clinical efficacy while avoiding potential side effects often associated with medications or surgery (Parker and Griebling, 2015).

Some older adults choose to limit fluid intake in an attempt to reduce urgency incontinence or urinary urgency or frequency episodes (Miller et al., 2011; Segal et al., 2011). Although this can be useful in select cases, particularly at night in those with symptomatic nocturia, care must be taken to avoid dehydration. **Reduced fluid consumption can exacerbate UI and constipation. In addition, restriction of fluids can lead to production of a stronger and more concentrated urine, which is actually more irritating to the epithelium.** Although total urine volume is reduced, increased urinary concentration can actually worsen urge symptoms. Other common dietary recommendations including avoidance of foods or beverages that tend to trigger urinary urgency and frequency symptoms. These include caffeine, carbonated beverages, alcohol, and spicy or acidic foods (Gleason et al., 2013).

Timed or scheduled toileting can be useful in some patients with urinary urgency and frequency. Many older adults have worse symptoms near bladder capacity. **Voiding on a more regular schedule before reaching capacity may help to limit urge sensations and associated leaking.** Bladder retraining, a series of steps to increase the intervoiding interval, can also be useful in select cases. This can help to slowly increase functional bladder capacity and response to sensations of bladder filling. One clinical trial demonstrated a mean reduction of 57% for urgency incontinence frequency in elderly women (Fantl et al., 1991). Delayed voiding is similar except that patients do not follow a predetermined time interval but instead base their schedule on sensations as they experience them (Burgio et al., 2011). Biofeedback training is sometime used in combination with this type of intervention (Newman, 2014). Urge suppression methods are frequently combined with other types of therapy as a form of habit retraining to improve UI symptoms (Ostaszkiewicz et al., 2004).

PFME is one of the primary forms of behavioral therapy used to treat UI in older adults. Numerous studies have shown that men and women with various types of UI can benefit. However, simply telling people to do Kegel or pelvic muscle exercises is unlikely to be successful. **Most older adults require specific training for these methods to work.** Cognitive impairment may limit practicality of this therapy in some patients. It requires a motivated patient who is willing to do the exercises and is able to follow guided instruction. In a study of hospitalized older women (mean age 78.2 ± 6.3 years), the majority (74.5%) were unable to voluntarily contract their pelvic floor muscles (Talasz et al., 2012). With proper instruction, PFME has been shown to improve UI more than just bladder training and timed voiding alone (Sherburn et al., 2011). PFME is often used in combination with other forms of behavioral or pharmacological therapies, and effects may be additive or synergistic (Burgio et al., 2000; Ghoniem et al., 2005). In some cases, patients may be able to decrease or discontinue medications for UI, depending on success of PFME and behavioral treatments (Burgio et al., 2008). It has also been shown to be effective in men with a history of postprostatectomy incontinence and in patients with symptomatic nocturia (Goode et al., 2011; Johnson et al., 2005).

PFME appears to have a direct effect on pelvic anatomy and physiology. It has been shown to improve pelvic floor muscle morphology and dynamic function over time (DuMoulin et al., 2009; Madill et al., 2013). A variety of teaching methods have been developed and advocated for PFME instruction in older adults. These have been used successfully in nursing home settings (Engel et al., 1990; Vinsnes et al., 2012). Group instruction is feasible and has been shown to have good outcomes (Lajiness et al., 2007; Sampselle et al., 2005). This may be particularly useful for older adult patients who may benefit not only from direct instruction but also from interaction and support of the group learning PFME together. It may also be a more efficient and cost-effective way to disseminate this type of clinical education for multiple patients. This has been shown to be effective in a nursing home setting where participants also experienced improvements in overall functional status (Tak et al., 2012). Online instruction with Internet-based teaching and interactive support forums have been shown to be successful in early trials (Sjöström et al., 2013).

Vaginal cones can be used to augment pelvic floor exercise and may help patients to identify the muscles used in this technique. However, randomized controlled trials have not shown statistically significant differences in continence outcomes with or without cones (Pereira et al., 2012, 2013). Electrical stimulation of pelvic floor muscles can also be used, but results of this treatment compared with PFME alone have been mixed (Castro et al., 2008; Correia et al., 2014). Weight loss has been shown to be effective at improving stress UI and FI in elderly women with obesity (Markland et al., 2011; Subak et al., 2009).

Pharmacotherapies.

Medications are widely used in treatment of UI. The specific drug selected is typically based on the type and cause of UI experienced by the patient. Unfortunately, there are currently no pharmacologic agents available in the United States that are particularly effective for treatment of stress UI in older adults. Medications with alpha agonist properties such as pseudoephedrine have been tried but tend to have substantial side effects and limited clinical efficacy in geriatric patients. The older medication phenylpropanolamine was removed from the market by the FDA because of increased risk of serious side effects including hemorrhagic stroke and other thromboembolic events (Meadows, 2001). Duloxetine, a balanced serotonin and noradrenaline reuptake inhibitor, also has α-adrenergic properties and has been considered as a possible treatment option for stress UI (Basu and Duckett, 2009). Although it is used in some parts of the world, it is not approved by the United States FDA for this purpose.

The majority of medications have been designed to treat OAB, including urinary urgency, frequency, and urgency UI. These are mostly antimuscarinic, anticholinergic medications that act by blocking muscarinic receptors in the bladder, which in turn decreases detrusor contractions. The classic medication in this group is oxybutynin. Although it can be effective for management of bladder symptoms, it has strong anticholinergic properties, which can cause problematic side effects in older adults. The most common include dry mouth and constipation, although dry eye, headache, confusion, and other anticholinergic effects may also occur (Moga et al., 2013; Pagoria et al., 2011). It is important to remember that a wide variety of medications may cause dry mouth and other adverse effects (Tan et al., 2018). **Some of the newer selective antimuscarinic agents and the β_3 agonists may help reduce these problems.** These medications can be used in men and women, and all have been shown to have relatively similar efficacy (Madhuvrata et al., 2012).

Several of the newer medications have theoretical advantages for use in older adults. In some cases these may have a real physiologic effect, but to some extent the primary purpose has been differentiation in marketing for various drugs. Differences between medications have been based on a variety of factors including lipophilicity, molecular size, selective affinity for various muscarinic receptor subtypes, drug half-life, and other metabolic effects. For example, trospium is a quaternary amine, unlike the other agents which are tertiary amines. Animal studies have shown that trospium may be less likely to cross the blood-brain barrier and may therefore decrease the potential cognitive side effects from this medication (Kranz et al., 2013). However, changes in the blood-brain barrier with aging increase permeability and may alter drug efflux in older adults (Chancellor et al., 2012). Studies of these types of medications in older adults must examine cognitive side effects (Kay et al., 2006; Paquette et al., 2011). Improved selectivity of muscarinic receptor binding is another focus in drug development. The goal is to target the bladder (M_2 and M_3) but avoid the salivary gland and bowel (both M_3), which may help reduce the risk of dry mouth and constipation (Abrams and Andersson, 2007).

The route of administration and type of drug delivery system are also important considerations for several of these medications. These can influence pharmacokinetics and pharmacodynamics of these preparations. Immediate release drugs offer quick onset of action, but long-acting or time-released agents may have a benefit of more stable steady-state of circulating medication. Transdermal preparations avoid the first pass effect through the liver and may be useful in patients with hepatic insufficiency. They are also useful in patients with swallowing difficulties that can prevent effective use of oral tablet or capsule formulations. Liquid oxybutynin is available and can be administered through feeding or gastric tubes in patients unable to swallow liquids or other formulations.

One of the challenges is that older adults are frequently excluded from clinical trials used to approved medications and other treatments because of their underlying comorbidity and heterogeneity (Beers et al., 2014; Briggs et al., 2012). **However, the reality is that these drugs are widely prescribed in this type of patient population in routine clinical practice** (Kraus et al., 2010). This means that potential side effects and interactions between medications and underlying comorbidity have been studied in less detail, which makes clinical decisions and prediction of outcomes more difficult. **Several recent studies have examined use of antimuscarinic medications specifically in older adult cohorts.** Fesoterodine was demonstrated to have good clinical efficacy in a 12-week randomized, placebo-controlled trial in a group of 562 elderly patients with a mean age 75, and 50.4% 75 years old or older (DuBeau et al., 2014). This group had high baseline rates of comorbidity, polypharmacy, and functional impairment, which mirror real-world prescribing challenges. The medication was generally well tolerated, and overall adverse events were similar to those seen in younger patient populations. These results were also demonstrated in a similar trial of fesoterodine conducted with geriatric patients in Europe (Wagg et al., 2015). This medication has also been shown to be safe in older women with hypertension (Yokoyama et al., 2018). Studies on older adults have also shown relatively good efficacy and tolerability for tolterodine, solifenacin, darifenacin, and trospium (Chapple et al., 2007; Griebling et al., 2009c; Lipton et al., 2005; Sand et al., 2011; Wagg et al., 2006, 2013). One study of fixed low-dose, extended-release oxybutynin in cognitively impaired older adults living in nursing homes did not seem to worsen cognition and decreased the number of wet pad checks by 38% but failed to show a significant benefit for UI overall

(Lackner et al., 2011). An earlier study had also shown relatively good tolerability with no increase in rates of delirium in a cohort of cognitively impaired nursing home residents (Lackner et al., 2008).

Most of these medications undergo either hepatic or renal metabolism, and caution is warranted in patients with liver or kidney impairment. Use of the lowest clinically effective dose is generally recommended. Drug-drug interactions tend to occur with other drugs that undergo hepatic metabolism. Drug-food interactions have also been identified, particularly with alcohol and grapefruit, which can lead to inhibition of the cytochrome P450 pathway. **Use of the antimuscarinic and anticholinergic medications is also contraindicated in patients with closed angle (narrow) glaucoma.** Consultation with a patient's ophthalmologist or optometrist may be needed in these cases before prescribing these medications. Open-angle glaucoma is much more common, and this by itself is not a contraindication to use of the antimuscarinic anticholinergic medications for treatment of urinary symptoms.

Adverse effects of antimuscarinic medications are one of the primary limiting factors for ongoing use, particularly among older adults (Sears et al., 2010; Wagg et al., 2012). Discontinuation of medication is common, and several different medications may have to be tried to find one that is acceptable for an individual patient. Urinary retention is a theoretical risk with all of these medications, although this is not commonly seen in clinical practice. Monitoring of postvoid residual volumes after initiation of therapy may be considered.

A new class of agents for treatment of OAB are β_3-adrenoceptor agonists. Mirabegron is the only agent in this class currently approved in the United States and is available in 25-mg and 50-mg doses taken once daily. This acts on detrusor smooth muscle to decrease contractility and reduce symptoms associated with overactivity. Studies in older adults have demonstrated good clinical efficacy with relatively few side effects (Lee and Kuo, 2018; Wagg et al., 2014). Although some data suggest it can increase blood pressure, this medication has been demonstrated to be safe in general from a cardiovascular perspective (Rosa et al., 2016). This class of medications offers the potential advantage of reducing bladder symptoms without the risk of anticholinergic side effects.

Regimen compliance and continuation can be problematic with the antimuscarinic medications, particularly among older adults. Discontinuation rates are relatively high, ranging up to 50% to 86% at 1 year (Mauseth et al., 2013; Sicras-Mainar et al., 2014; Wagg et al., 2012).

Newer data suggest that these rates may be even lower at around 30% at 1 year (Kosilov et al., 2017). Although all of the available medications have been shown to be effective in clinical trials, the response of an individual patient to a specific medication is difficult if not impossible to predict. Patient perception of the degree of improvement is very important in their decision to continue or stop pharmacotherapy (Basra et al., 2008). Older adults frequently discontinue these types of medications because of either a lack of perceived efficacy or development of adverse effects such as dry mouth, constipation, or confusion.

Cost is also an important consideration when using pharmacotherapy for UI in older adults (Armstrong et al., 2012; Perimenis et al., 2006). Many geriatric patients are on a fixed income, and they may or may not have insurance coverage for prescription medications. Coverage varies widely among different policies and between different drugs. Even under Medicare Part D benefit, older adults may have a substantial out-of-pocket expense, particularly if they are on multiple medications and have used the extent of their available benefits. Different medications may have different preferred formulary status with different coverage plans. Patients often need help navigating these complexities with their insurance providers and pharmacies.

Use of antimuscarinic medications in patients with underlying cognitive impairment, or dual use in those on cholinesterase inhibitors requires special consideration. These drugs theoretically act in pharmacologic opposition and may influence symptoms of the other disease process (Green et al., 2017). There have been anecdotal reports of patients developing UI after initiation of a cholinesterase inhibitor, and conversely cognitive decline has been reported in some patients after initiation of an anticholinergic medication for treatment of urinary symptoms (Hashimoto et al., 2000; Siegler and Reidenberg, 2004; Starr, 2007). This can be associated with an increased risk of polypharmacy in these older adults (Modi et al., 2009). In fact **initiation of one medication may lead to symptoms that prompt subsequent prescription of the other class of medications, an example of the “prescribing cascade”** (Boudreau et al., 2011; Johnell and Fastbom, 2008). Larger observational studies have shown that combined use of these medications can lead to progressive cognitive decline in some older adults (Sink et al., 2008). In these cases, it can be helpful to consult directly with the treating geriatrician or neurologist to determine which medication should take priority based on the overall clinical situation. Risks and benefits of medications must be balanced with observed outcomes in regard to urologic and neurocognitive function. Risks of cognitive change or confusion with anticholinergic medications are real, although overall reported incidence is relatively small. Discontinuation of medication usually results in resolution of the cognitive side effects.

Potential cardiac risks are also a consideration with specific antimuscarinic agents. For example, high doses of tolterodine may cause Q-T prolongation that can lead to symptomatic bradycardia, and even Torsade de pointes. Maximum dosing for specific medications should be carefully considered and should not be exceeded (Rosa, 2013). Anticholinergic medications also have a potential risk of inducing tachycardia, although this has not been reported as a common clinical adverse event of currently available medications. The β_3-adrenoceptor agonist mirabegron has been associated with slight increases in blood pressure and should be used carefully in older adults with a history of hypertension (Sanford, 2013). Underlying cardiovascular disease plays an important role in these cases and should be considered when prescribing of medications for treatment of OAB.

Surgical Therapies.

A number of different forms of surgical therapy are used for treatment of UI in older adults. These include surgical procedures for stress and urgency UI. Many older adults want to avoid surgery as a possible treatment option for UI, POP, or other urologic conditions. Similarly, many clinicians may not consider surgical options for geriatric patients because of concerns about potential risks and complications resulting from age (Griebling, 2011). However, **there is a growing body of evidence that indicates surgery may be safe and effective for carefully selected older adults with UI and other genitourinary disorders. Age alone is rarely a significant risk factor for postoperative outcomes, which tend to be more closely related to comorbidity and functional status.** In fact, considering surgery earlier in the treatment algorithm may be appropriate in some cases. For example, prolapse repair performed earlier after menopause in older women has been shown to have improved outcomes compared with those in which surgery is substantially delayed (Ahn et al., 2010). Development of newer, less-invasive effective surgical procedures have made some surgical options more viable for use in elderly patients (Atiemo et al., 2006). In addition, efforts to better optimize older adults medically before surgery may help to improve outcomes (Chow et al., 2012).

Bulking agent injections have been used to treat stress UI in older women (Keegan et al., 2007; Lightner et al., 2002). They offer the advantage of a minimally invasive technique with relatively good success rates. However, overall success is somewhat more limited compared with other surgical techniques because of longevity of the effect and need to repeat the procedure. Conversely, the ability to repeat treatment can also be seen as a clinical advantage to bulking agent injections. A variety of materials have been used for this purpose including cross-linked bovine collagen, synthetic gels, and microbeads (Khullar et al., 1997; Lightner et al., 2001; Vecchioli-Scaldazza et al., 2014; Winters et al., 2000). **Bulking agent injection therapy may be particularly appealing in elderly women with stress UI who may not be candidates for more involved surgical therapy.** The use of bulking agents in men has shown substantially less overall success compared with efficacy in women (Griebling et al., 1997).

Sling procedures are used for treatment of stress UI. Slings for treatment in women include pubovaginal and mid-urethral procedures. Various graft materials have been used for this purpose, including autologous fascial grafts, other biologic grafts using either cadaveric fascia or xenografts, and synthetic mesh. Slings have also been developed for treatment of stress UI in men. There have been a number of published studies that have examined safety and efficacy of sling procedures for treatment of stress UI in geriatric patients. These have generally shown good outcomes with no significant difference in complication rates compared with younger patients (Jun et al., 2012; Serati et al., 2013; Stav et al., 2010). However, other clinical reports suggest older women may be at increased risk for perioperative UTIs and other complications (Groutz et al., 2011). Continence outcomes may also differ with one study reporting inferior rates of improvement in elderly women compared with younger patients after mid-urethral mesh sling (Kim et al., 2011). In this study, elderly women had higher rates of parity, hysterectomy, and prior anti-incontinence or prolapse surgery. This could have influenced observed results. An analysis of Medicare beneficiary data demonstrated that elderly women appear to have a higher risk of urinary retention, urinary urgency, and other complications after sling surgery compared with younger women (Anger et al., 2007a, 2007b). Some surgeons may avoid using mesh specifically in elderly women because of potentially increased risks of erosion or other complications after this type of surgery (Reynolds et al., 2013).

Artificial urinary sphincter (AUS) implantation is often used for treatment of stress UI in men. AUS devices are not commonly used in women any longer because of advances in sling procedures, bulking agent injections, and other minimally invasive surgical options. Cognitive status and manual dexterity must be carefully considered in elderly men being considered for AUS placement because they will need to operate the device several times daily to effectively manage incontinence and void. In select patients this therapy can be effective (O'Connor et al., 2007). Sling procedures for treatment of UI in men have been developed, but there are no clinical data examining outcomes specifically in geriatric patients.

Neuromodulation uses electrical stimulation of the nerves that control detrusor contractility to treat voiding dysfunction. Two forms of neuromodulation are currently available, including sacral neuromodulation with implantable electrodes (InterStim, Medtronic) or peripheral tibial nerve stimulation (Urgent PC, Uroplasty). Both have shown good success in research trials and clinical practice. Studies on use of these therapies in geriatric patients have been somewhat limited; however, reported results are promising (Griebling, 2010; Schreiner et al., 2010; White et al., 2009). Success rates up to 83.3% at 1 year have been reported in geriatric patients among those who went on to generator placement (Angioli et al., 2013). Reported complication rates are low, even in elderly patients with multiple comorbidities (Chughtai et al., 2015). Age by itself does not appear to substantially influence overall success of therapy (Peters et al., 2013). Posterior tibial nerve stimulation has been used successfully for older adults in a residential care setting, and in patients with a history of voiding dysfunction related to prior stroke (Booth et al., 2013; Monteiro et al., 2014). Successful use of neuromodulation therapy requires that the patient be able to identify characteristics of his or her symptoms and participate in ongoing programming and adjustment of the device as needed. In some cases, if patients are unable to do this themselves, assistance from a caregiver may be required.

Chemodenervation of the detrusor muscle is used to treat urinary urgency, frequency, and urgency UI. This has typically been reserved for use in cases that are refractory to other forms of therapy, including behavioral or pharmacologic interventions. The most commonly used agent for this purpose is onabotulinumtoxin A. Studies in older adults have been relatively limited but have shown clinical efficacy and overall safety (White et al., 2008). The major concern of this particular therapy is the risk of urinary retention, which could necessitate CIC or indwelling catheter drainage at least temporarily.

Urinary diversion is another possible option for treatment of intractable UI in highly selected older adults. In some elderly patients, use of a urinary conduit with management of a stomal appliance is preferable to UI. **Care must be taken**

to evaluate potential risks of surgery and balance this with the potential benefits of independent urinary control provided by urinary diversion (Osborn et al., 2014). In select patients, creation of a continent catheterizable diversion may also be an option (Gowda, 2008).

Use of indwelling catheters is generally avoided in older adults because of associated risks of UTI, catheter colonization, urinary tract stones, or tissue erosion (Drinka, 2006; Leuck et al., 2012; Ouslander et al., 1987). Chronic use of indwelling catheters after discharge from acute hospitalization in older adults has been linked to negative outcomes including an increased risk of mortality (Holroyd-Leduc et al., 2007). Catheters should be removed as soon as feasible to help prevent these negative outcomes. Indwelling catheters are also not particularly helpful in management of DO because they tend to exacerbate bladder contractions and can make symptoms worse. They should also be avoided for simple convenience or fluid monitoring in most patients in acute care settings.

However, use of indwelling catheters can be useful in highly select cases. These include patients with chronic urinary retention and incomplete bladder emptying who are unable to undergo CIC for various reasons. Other examples include those with morbid obesity, severe extremity contractures, or other body habitus changes that prevent catheterization. Older adults with dementia or severe cognitive impairment, severe urethral stricture disease not amenable to surgical correction, or other anatomic changes may not tolerate CIC. In this case, use of an indwelling catheter may be more appropriate. Patients with sacral pressure ulcers or other skin breakdown may also benefit from temporary indwelling catheter drainage to keep the affected area dry and allow for tissue healing. Temporary urinary catheter drainage can also be useful after flap placement or other reconstructive surgery to keep the surgical site dry during the healing process.

In cases in which chronic catheterization is necessary, placement of a suprapubic catheter is generally preferred over urethral catheterization. This helps prevent bladder neck and urethral erosion in all patients and decreases rates of epididymitis and prostatitis in men. Once the tract is healed, the suprapubic tube may be easier for staff to change and may also be more comfortable for the patient. This also positions the catheter out of the urethra and genital tract and allows patients to be sexually active if so desired. The catheter should be changed at least monthly or more often if necessary based on individual clinical variables (Wilde, 2013). Cystoscopy is generally recommended on at least an annual basis, particularly after the first several years of use, to evaluate for any mucosal changes such as squamous metaplasia or development of stones. **If patients have problems with urinary leakage around the catheter or from the urethra, treatment should be focused on reducing bladder contractions with antimuscarinic or other agents and ensuring adequate catheter drainage. It is strongly recommended that providers NOT increase the caliber of the tube.** Increasing the diameter of the catheter will not solve the underlying cause of the urinary leakage and will only dilate the suprapubic (SP) tract or urethra. This can lead to severe problems with erosion and catheter extrusion. Catheters of 16 or 18 Fr are generally adequate for use as an SP tube.

Urine Containment and Absorbent Products.

A variety of devices and products are available to help manage urinary leakage. Although these should not be considered a curative treatment option, they can be useful for management of symptomatic urine loss. In some cases, use of these types of products can allow affected individuals opportunity to participate in social activities they would otherwise avoid because of embarrassment or other factors associated with UI.

Absorbent pads and products come in a wide array of designs. These range from small pads to extra absorbent briefs and can be used for light and heavier volumes of urinary leakage (Fader et al., 2007, 2008). There are some differences in products available for men and women with designs specific for leakage target zones based on anatomy. Advances in technology have continued to improve products, including better management of odor and absorbency (White et al., 2003). Gel-based products may offer better odor control and have good overall absorbency, although they may not be able to control large volume leakage as well as products using wood pulp or fiber. Pads may be particularly effective in helping to reduce associated dermatologic complications such as urea dermatitis of the perineum (Sugama et al., 2012). Pads and absorbent products are frequently used in the UI management scheme of nursing home residents and can be a useful adjunct in this setting (Pfisterer et al., 2007). Use in acute care settings should be relatively limited if possible and has been shown to potentially increase rates of UI (Zisberg et al., 2011).

Condom catheters, also known as urinary sheaths, can be a useful adjunct for management of urinary leakage in men. These disposable devices surround the penis and are connected to a urinary drainage collection bag. Some men use these in selective settings such as when they go out of their home or participate in social activities. They can also be used at night to help control urinary leakage and decrease bother from nocturia, particularly in men with mobility limitations that make traveling to the toilet difficult or dangerous. Proper sizing of condom catheters and good skin hygiene are essential for successful use. Skin breakdown or necrosis can occur if the device is not properly maintained or if the condom is too small or placed too tightly around the penile shaft.

Urethral clamps and plugs are available in a wide variety of styles. Cunningham and other types of penile clamps should be used only during the daytime and must be moved to different locations on the penile shaft every few hours to prevent tissue injury or necrosis. Men need to have adequate hand dexterity and cognitive function to use these types of devices successfully. Urethral caps and plugs have been developed for use in women. These offer the advantage of a nonsurgical option but can be difficult to use because of disposable design, which requires removal and replacement with every void and associated costs. They also require adequate hand dexterity for routine use. These types of devices may be most useful when used selectively to prevent urinary leakage during exercise or other physical activities, or when leaving the home environment.

Other Lower Urinary Tract Dysfunction, Urinary Tract Infections, Pelvic Floor Conditions, and Genitourinary Trauma

A wide variety of other lower urinary tract and pelvic floor conditions can affect older adults and require special considerations for geriatric patients.

Bladder Outlet Obstruction

BOO, particularly resulting from BPH or urethral stricture disease, is more common in elderly than in younger patients. Incidence and prevalence rates for BPH, UI, and other forms of voiding dysfunction in men increase with advancing age (Griebling, 2008; Irwin et al., 2011; Parsons et al., 2008). Evidence-based guidelines for evaluation and management have been developed (McVary et al., 2011). However, there still appears to be a bit of variation in initial evaluation and management among different practices (Erickson et al., 2014; Strope et al., 2011).

Measurement of PVR volume is a key component of most evaluations, but how this changes with time is somewhat unclear. Recent population-based data suggest that for men with initially low PVR measurements, few will require future treatment compared with those with baseline PVR of more than 400 mL in whom 75% needed intervention over time (Noguchi et al., 2018).

The spectrum of medical and surgical therapies should be considered, and decisions based on each patient's unique situation. In many cases, men want to start with medications before considering surgical therapy. Recent research has led to an increased use of combination therapy with alpha-blockers and other forms of medication, including PDE-5 inhibitors, antimuscarinic agents, and 5-alpha-reductase inhibitors (Chung et al., 2011; Regadas et al., 2013).

Tissue ischemia caused by oxidative stress and diminished blood flow to the pelvic organs and prostate is a factor, which theoretically could worsen BOO symptoms. Animal studies have suggested that an antioxidant diet may help to reduce the negative effects of this condition (Bisogni et al., 2012). There is great interest to determine if similar results may be possible in humans.

Surgical therapies can be very useful, particularly in men with a history of acute urinary retention resulting from BOO, or in those who have not experienced sufficient improvement on pharmacotherapies. In addition to traditional transurethral resection, laser surgery and other minimally invasive forms of therapy have been used successfully in elderly men with BPH (Elshal et al., 2013; Kuntz et al., 2008). Bipolar plasmakinetic TURP has been used to reduce bleeding during surgery in elderly men with larger prostate glands (Coskuner et al., 2014). However, TURP may not be successful in all elderly men. In fact, a recent study showed 64% of elderly male nursing home residents who were underwent TURP for urinary retention were still catheter dependent postoperatively, and 32% died in the first year after surgery (Suskind et al., 2017). There has also been some early interest in embolization of the prostatic arteries as a minimally invasive therapy for symptomatic BPH (Wang et al., 2016).

Care must be taken when considering treatment of elderly men with BPH, particularly in those with associated neurologic conditions such as Parkinson disease, Shy-Drager syndrome, multiple sclerosis, or other underlying disorders. These can exacerbate bladder storage and voiding problems and may increase risk for UI and other negative outcomes. Even after relief of BOO, DO may not completely resolve. This can be frustrating to patients and may continue to require therapy to control bothersome symptoms. TURP has traditionally been avoided in men with combined BOO and detrusor underactivity, although newer data have been challenging this long-held concept (Ou et al., 2012).

In select patients who are not good surgical candidates, urethral stents may be considered as an option (Milroy and Allen, 1996). Complications of urethral stents include technical issues and difficulty with tissue overgrowth and urethral strictures. However, in select men who may otherwise be dependent on indwelling catheter drainage, urethral stents may offer a viable treatment alternative (Bozkurt et al., 2013; Gesenberg and Sintermann, 1998). Urethral reconstruction may be feasible in select elderly men, and good outcomes have been reported using dorsal onlay skin grafts among other techniques (Schwentner et al., 2010).

Ophthalmic side effects of medications used to treat BOO must be considered carefully in elderly men. The “floppy iris syndrome” is a condition that causes billowing of the iris during surgical cataract extraction and lens implantation (Bell et al., 2009; Friedman et al., 2009). It is important that elderly men on tamsulosin and other medications for treatment of BOO inform their eye surgeon before any procedure. These medications may have to be discontinued for at least a week before planned cataract surgery.

Underactive Bladder, Neurogenic Bladder, and Urinary Retention

Underactive bladder (UAB) is a condition characterized by poor bladder emptying that is not necessarily caused by BOO. It likely encompasses multiple causes and clinical conditions (Taylor and Kuchel, 2006). This may be related to a failure of the detrusor muscles to contract and a failure of the neural pathways to properly stimulate the bladder (Smith, 2010). The ICS defines the term *detrusor underactivity* as “a contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete emptying within a normal time span” (Abrams et al., 2002).

Research on UAB is relatively new, and there are few epidemiologic studies on the condition (Griebling, 2013a). In a population-based survey, 23% of 633 respondents indicated they had difficulty emptying the bladder (Valente et al., 2014). In a similar study of older adults who had undergone urodynamic testing for voiding dysfunction, 40.2% of men and 13.3% of women were diagnosed with detrusor underactivity (Jeong et al., 2012). **Structural and functional changes appear to lead to development of underactive bladder.**

Ultrastructural studies have demonstrated that aging is associated with an increased deposition of collagen and a reduction in the ratio of smooth muscle to connective tissue (Elbadawi et al., 1993, 1997).

Progression of prior OAB or BOO may be involved in this process (Chancellor, 2014). Alterations in active contraction and passive muscle stretch appear to play an important role as well (Young et al., 2013). Bladder ischemia has been linked to subsequent development of detrusor dysfunction and UAB. Studies using color flow Doppler ultrasound have shown there is a quantifiable decrease in pelvic arterial blood flow in some elderly patients with LUTS. This may be due to atherosclerosis or other vascular insufficiency (Kim et al., 2010; Pinggera et al., 2008). The development of animal models of UAB will help advance future research on this topic (Tyagi et al., 2014a).

Several different forms of UAB have been identified in geriatric patients, and this can manifest in several different ways. Detrusor failure can be caused by sacral nerve injury with development of cauda equina syndrome. Patients typically experience lower extremity weakness and problems with gait and mobility. Some may develop frank paraplegia. In these cases, the bladder typically has a low pressure during filling and does not contract well to void.

Acute urinary retention can be caused by BOO or detrusor failure. Decompression with an indwelling urinary catheter is usually required initially with careful monitoring for postobstructive diuresis and electrolyte fluctuations. Evaluation for renal insufficiency or hydronephrosis is also warranted. **Avoid catheter clamping before removal because this has not been shown to be of any clinical benefit and will only induce discomfort.** In men with a history of BOO from BPH, initiation of medical therapy with alpha-blockers or 5-alpha-reductase inhibitors can be considered.

DHIC is one of the more common conditions seen in geriatric practice (Resnick and Yalla, 1987; Yalla et al., 2007). This condition is characterized by urinary urgency and frequency resulting from DO during bladder filling and storage. However, during the voiding effort, the bladder contracts poorly and does not empty well. Because of this, patients experience urinary urgency and frequency but incomplete voiding and urinary retention.

Adequate treatment of UAB can be complex. In many cases, this may require intermittent bladder catheterization. However, in some patients this may be difficult or impossible because of comorbidity such as severe hand arthritis or cognitive impairment. Augmented voiding techniques including the Credé maneuver or bladder tapping may be used by some patients (Ersoz et al., 2013). Care should be taken to monitor the upper urinary tracts in these patients for development of hydronephrosis or other evidence of clinical deterioration.

Unfortunately, there is currently no effective pharmacologic therapy that improves bladder emptying in the case of underactive bladder. Theoretically, the cholinergic medications should lead to improved smooth muscle contraction in the urinary bladder. But **medications such as bethanechol have failed to demonstrate clinically efficacy.** A recent Cochrane review concluded that this medication should not be used for the treatment of urinary retention or underactive bladder (Lapitan et al., 2013).

Early qualitative studies have demonstrated the negative impacts on overall and health-related quality of life in people with UAB (Uren et al., 2017). Continued research and education on UAB will help advance our understanding of the clinical condition in geriatric patients (Dewulf et al., 2017; Griebling et al., 2014b).

Spinal cord injury is also a major cause of voiding dysfunction including urinary retention in older adults. Neurogenic bladder management with urinary retention typically involves CIC in patients who are able to do this. However, some patients with spinal injuries may require urinary diversion. The overall clinical needs of geriatric patients with neurogenic bladder resulting from spinal cord injury must be considered in the context of their overall health, and particularly their comorbidities and functional status (Chan et al., 2018).

Nocturia

Nocturia is one of the most common and bothersome urinary conditions that occurs in elderly patients (Wehrberger et al., 2012; Weiss and Blaivas, 2000). The ICS defines nocturia as “getting up from sleep in order to void” (Abrams et al., 2002). This is generally preceded and followed by additional episodes of sleep. Polysomnography studies have documented that a majority of episodes of nocturia occur during superficial rapid eye movement (REM) sleep (Bal et al., 2012; Krystal et al., 2010). However, waking to urinate can also lead to difficulty getting back to sleep with 46% of older adults in one survey reporting this as a substantial clinical problem (Endeshaw, 2009). Affected older adults also report worse disease burden, poor overall sleep quality, and an increased rate of falls compared with those who fall back to sleep more easily. Sleep duration is often decreased in older adults, and this has been identified as an independent risk factor for nocturia in elderly patients (Udo et al., 2009). Several biochemical processes appear to influence nocturia and nocturnal polyuria. Obstructive sleep apnea results in decreased antidiuretic hormone (ADH) secretion and increased brain natriuretic peptide (BNP), which can lead to nocturnal polyuria (Hoshiyama et al., 2014). Nighttime melatonin secretion is inversely proportional to nocturia in older adults (Obayashi et al., 2014). Worse nocturia severity has also been linked to progression of underlying neurologic disorders such as Parkinson disease (Vaughan et al., 2013). Improved understanding of these complex associations between comorbid conditions and nocturia may help to improve future options for diagnosis and treatment.

The epidemiology of nocturia is complex and is linked to underlying risk factors associated with the condition. There appear to be some underlying differences in nocturia between men and women resulting from a variety of anatomic and physiologic factors (Bing et al., 2007, 2008; Tikkinen et al., 2006). An epidemiologic survey of 6000 people in Finland revealed multiple associated conditions, including urinary urgency, snoring, BPH in men, and overweight and obesity (Tikkinen et al., 2009). At an individual level, urinary urgency appears to be one of the strongest correlated conditions. However, none of the conditions studies accounted for more than 50% of cases, even in age-adjusted risk analysis. Some modifiable behavioral factors have also been associated with nocturia, including alcohol consumption and cigarette smoking (Lee et al., 2012). Symptoms of nocturia can change over time and may resolve spontaneously in some cases (Pesonen et al., 2016).

Nocturia can have a substantial negative impact on quality of life. In general, one episode of nocturia per night is well tolerated by most people and is usually considered normal. However, **two or more episodes of nocturia nightly have been linked to diminished sleep quality, reduced overall and health-related quality of life, and other detrimental clinical outcomes** (Tikkinen et al., 2010). Nocturia has also been linked to depression in longitudinal research (Obayashi et al., 2017). Increased rates of morbidity and mortality have been linked to nocturia (van Doorn et al., 2012). **Worse nocturia severity has been directly correlated with increased rates of complication including falls, fractures, and other negative clinical outcomes** (Bing et al., 2007, 2008). This association appears to be independent of age and is more associated with severity of nocturia (Temml et al., 2009). This is true in community-dwelling older adults and those living in nursing homes and other facilities (Galizia et al., 2012). **Falls are associated with increased rates of hip and long bone fractures, which in turn increase the risk for immobility and mortality** (Nakagawa et al., 2010). Fat embolization from bone fractures can cause stroke and pulmonary embolus. Falls associated with nocturia can be caused by a number of factors, including problems with balance and gait, attempting to travel to the toilet in the dark, navigating obstacles that may be in the path to the bathroom, and other factors.

Even in younger people, increased rates of nocturia have been associated with increased mortality (Fitzgerald et al., 2007; Kupelian et al., 2011; Nakagawa et al., 2010). **This is likely due to the fact that nocturia may be a marker condition of other comorbid diseases,** including cardiovascular and pulmonary diseases among others. Elderly patients with nocturia who also suffer from being underweight are at increased risk of mortality compared with heavier patients (Negoro et al., 2015).

A careful history is useful in helping to identify potential causes of nocturia. Multiple different conditions can contribute to nocturia (Denys et al., 2017). These include nocturnal polyuria, medications that increase urine production or disrupt sleep, diabetes insipidus, the syndrome of inappropriate antidiuretic hormone (SIADH) production, hypertension, congestive heart failure, pulmonary or peripheral edema, obstructive sleep apnea, and other sleep-related disorders (Burgio et al., 2010; Guilleminault et al., 2004). A fluid intake and output diary can be helpful in differentiating causes of nocturia in many older patients.

Successful treatment of nocturia in elderly patients can be challenging and complex. **Because the cause of nocturia is typically multifactorial, single therapies provided in isolation are often ineffective, and multimodal therapy targeting different causes may be required.** Behavioral therapies and medications have been shown to be more effective in combination and should be focused on the underlying mechanisms of nocturia (Vaughan et al., 2009). Behavioral strategies that have shown promise include limiting evening fluid consumption, PFME training, delayed voiding methods, and urge-suppression techniques (Johnson et al., 2013). Use of diuretics during the earlier portions of the day may help to off-load excess fluid. Patients with peripheral edema may benefit from lying in a recumbent position earlier in the day to create a postural diuresis and offload some of this excess fluid before retiring to bed for the night. Use of pressure gradient stockings may also be helpful.

Obstructive sleep apnea is often treated with continuous positive airway pressure (CPAP) ventilation support. In patients with incomplete bladder emptying and nocturia, CIC performed at bedtime may permit better sleep by improving functional bladder capacity at night, thus allowing the bladder more time to fill during sleep. Use of assistive devices such as bedside commodes or handheld urinals can help to reduce difficulties associated with nocturia in older adults. This can be particularly useful in those with mobility limitations or where there is a strong risk for falls during nighttime toileting.

Desmopressin has been advocated as a potential pharmacologic treatment for nocturia caused by nocturnal polyuria. The overall expression of vasopressin receptors appears to increase with aging in the urinary bladder and the kidney (Birder et al., 2018). This makes it a potential pharmacologic target for treatment of nocturia. However, substantial caution should be exercised when using this medication, particularly in geriatric patients. Older adults tend to have less capacity for compensatory regulation of electrolyte imbalance. Hyponatremia is one of the major risks associated with use of desmopressin in elderly patients (Rembratt et al., 2006; Weatherall, 2004). Development of clinically significant hyponatremia can occur even several months after starting medication (Bae et al., 2007). In addition to potential hyponatremia, there are multiple other potential contraindications for use of vasopressin in older adults. These include risk of exacerbation of underlying heart failure, renal insufficiency, alterations in potassium and calcium excretion, and other electrolyte disturbances.

The primary risk is hyponatremia, which can be profound in some cases and can lead to negative outcomes including agitation, confusion, or coma. Staggered dosing of desmopressin and furosemide has been shown in short-term research to improve outcomes and possibly reduce associated risks of electrolyte abnormalities (Fu et al., 2011). Newer formulations with rapidly dissolving oral preparations or “melts,” which do not require water consumption for administration may be associated with lower rates of complications. Low-dose therapy (<0.2 mg) appears to be effective in many cases (Song et al., 2014). Dosing requirements may differ in men and women because of underlying physiologic differences, with older women appearing to require lower baseline dosages (Yamaguchi et al., 2013). Desmopressin was actually added to the most recent Beers criteria as a medication to avoid in older adults based on older research data (American Geriatrics Society, 2015). Clinical trials of desmopressin for treatment of nocturia in elderly patients are ongoing. Early data from clinical trials suggest that newer formulations with minimal dosing may be safe and effective for treatment of nocturia in the geriatric population (Kaminetsky et al., 2018).

Bowel Dysfunction and Fecal Incontinence

Older adults commonly experience difficulty with bowel function. This can be caused by changes in motility, absorption, and other physiologic alterations associated with the aging process. Fecal impaction can actually appear to be diarrhea because of liquid material oozing around a stool bolus leading to fecal incontinence, particularly in those with low anal closure pressures. Elderly patients often experience dual bowel and bladder incontinence because the same neural pathway controls both of these processes. **Fecal incontinence (FI) can be particularly problematic among older adults** (Hayden and Weiss, 2011; Quander et al., 2005). Health care providers must specifically ask about bowel function during clinical assessment. Older patients may not voluntarily provide information regarding bowel problems because of embarrassment or other personal reasons. Increased levels of functional dependence and a variety of other factors are associated with increased risk of developing fecal incontinence, particularly among nursing home residents (Bliss et al., 2018; Jerez-Roig et al., 2015).

Reported prevalence rates of FI range from 17% of community-dwelling women over the age of 85 to 43% of elderly women residing in nursing home facilities (Townsend et al., 2013). More recent data confirm these prevalence rates with 17.3% of community-dwelling older adults reporting having experienced accidental bowel leakage (Gorina et al., 2014). Among those receiving home health care services, FI was reported by 13.1% of those aged 65 to 74 years, and 20.8% for those aged 85 years and older. Patients in hospice care have reported prevalence of UI of 9.9%, FI 24.0%, and dual incontinence 28.0% (Gorina et al., 2014). **UI is highly correlated with FI, and older adults with either one of these conditions are at increased risk for developing the other problem.** Rectal hypersensitivity and anatomic defects of the anal sphincter muscle complex have been identified as additional risk factors for development of FI (Lewicky-Gaupp et al., 2009).

Constipation and FI are highly prevalent among nursing home residents. In one study, 81.1% of elderly nursing home residents had an average of 3 bowel movements every 5 days, and only 29% were classified as continent (Schnelle et al., 2009). These rates improved substantially with 74% “continent” using relatively simple targeted therapies, including prompted toileting. Multimodal therapy may also be useful in older adults with UI and FI and has been shown to substantially reduce problems with constipation (Schnelle et al., 2010).

Continence Promotion and Advocacy

Education of patients and providers is a critical aspect of continence promotion for older adults (Newman et al., 2017). There are a number of common myths about UI in geriatrics that hamper appropriate evaluation and treatment in many cases. **UI should never be considered a normal or inevitable part of the aging process.** Patients and providers need to be aware that there are often treatments that can substantially improve and in some cases completely eliminate incontinence. Many of these successful therapies involve nonsurgical methods. Surgery may be an appropriate and successful treatment option for some select patients with specific clinical indications.

Enhanced public awareness may improve access to and use of care services. An analysis of data on more than 82,000 elderly Medicare beneficiaries demonstrated a 37% prevalence of UI, but only 41% of those who experienced UI had spoken with a health care professional about their symptoms (Chang et al., 2008). Some have argued that systematic screening for UI may be beneficial among older women (Visser et al., 2013). In a survey study, elderly women indicated that they did not seek help because they did not feel their symptoms were severe enough to justify treatment (73.4%), they had already found a way to cope with symptoms (57.3%), they thought UI was a normal part of aging (46.9%), they thought there was no cure or effective treatment available (23.8%), or their general practitioner did not ask about UI (20.3%) (Visser et al., 2012). These findings demonstrate that there is a role for improved public and professional education and a need for advocacy on this topic.

Targeted continence promotion programs for older adults have been successful in the community setting. These can increase knowledge among patients suffering from incontinence and have been shown to encourage help seeking and self-treatment behaviors (Tannenbaum et al., 2010). Evidence-based self-management tools have been developed and can be useful in this process for motivated patients (Holroyd-Leduc et al., 2011). Future research will help improve understanding of the best methods for dissemination of this type of information among older adults suffering from UI and other urologic conditions.

Pelvic Organ Prolapse

POP is a common clinical condition seen in elderly women. Incidence and prevalence of POP increase with advancing age, but like other conditions it should not be considered an expected or normal part of the aging process. **Risk factors for POP in elderly women include history of prior pregnancy and vaginal delivery, prior pelvic trauma, and changes in tissue quality and structure.** Biopsy studies have shown that with advancing age, there is a progressive loss of smooth and striated muscle and an increase in collagen and other connective tissues in the urogenital diaphragm (Betschart et al., 2008). Apoptotic changes in pelvic floor tissues also occur that can predispose to prolapse (Saatli et al., 2014). These changes lead to laxity of pelvic floor architecture and subsequent loss of support.

Evaluation of POP in elderly women requires careful history and physical examination. Many older women describe the sensation of a vaginal bulge. This is often worse after physical activity or in the late afternoon or evening after being up and about during the day. **Severe prolapse can be associated with difficulties with urination or defecation because of urethral angulation or anatomic changes in rectal configuration.** Some women, particularly with a large prolapse, describe a need to manually reduce the bulge with their fingers to void or defecate. The clinician should attempt to reduce the prolapse during pelvic examination. The position of the uterus if present, and the vaginal cuff should be assessed. Prolapse of the vaginal apex may require specific surgical fixation to either the sacrospinous or uterosacral ligaments.

Pessaries can be useful in treatment of POP in elderly women (Griebling, 2016a). These come in a wide variety of shapes and sizes and must be individually fit to the patient. When the pessary is correctly sized, the patient is usually unable to feel it in the vagina. If the pessary is too small, it will tend to fall out with physical activity or straining. If it is too large, the pessary will tend to be uncomfortable and may cause tissue irritation or erosion over time. Pessaries should be removed and cleaned periodically, and the tissue integrity checked (Khaja and Freeman, 2014). In patients with limited hand dexterity or cognitive impairment, this may require assistance from a care provider. Visiting nurse services can sometime help with pessary management. It is important that the pessary be routinely checked to avoid complications associated with neglect, including erosion into surrounding structures or vaginal infections. Concomitant use of vaginal estrogen can be useful to help prevent some of these complications.

Pessaries offer potential advantages of avoiding surgery and allowing patients self-control over the clinical situation. Many older women do very well with pessaries and will continue to use them over time (Ramsay et al., 2016). Factors associated with increased long-term success include age of at least 72 years, careful fitting, and provision of clear instructions for use (Friedman et al., 2010). Successful pessary use has been associated with improved overall and health-related quality of life and improved body image in elderly women with POP

(Patel et al., 2010). However, some older women do not like using pessaries or do not want to be bothered with having to remove and replace the device on a regular basis. If the pessary improves genitourinary symptoms but the patient does not like using the device, this may indicate that she could experience a good functional outcome with surgery.

Surgical repairs for POP are feasible even in elderly women, and most women recover to their baseline functional status after surgery (Oliphant et al., 2014). These procedures can be done using vaginal, laparoscopic, robotic, or open surgical techniques. A variety of native tissue repairs and procedures using biologic or mesh grafts can be used. Several studies have shown that mesh repairs can be successful for treatment of POP even in elderly women (Gabriel et al., 2010; Shah et al., 2004). However, as with any surgical treatment, patients do have to be very carefully counseled about use of mesh grafts and potential risks and benefits associated with this technique (Mohammed et al., 2013; Reynolds et al., 2013). Surgical repair with native tissue grafts such as autologous or cadaveric fascia has also been successfully used in elderly women with POP and UI (Carey and Leach, 2004). Many older women may choose to avoid or delay surgery for POP. However, in those who do eventually undergo surgical repair, there is evidence to suggest that increased time between development of symptoms, particularly after menopause, and subsequent surgery is associated with poorer subjective postoperative improvements (Ahn et al., 2010). Recent data show low rates of complications (5.6%) for elderly women undergoing surgical repair for POP (Körnig et al., 2018).

One surgical option that can be considered for select older women with POP is colpocleisis with perineoplasty. This procedure essentially reduces the prolapse and closes the vaginal introitus. This should be considered a permanent and nonreversible procedure. Two different surgical techniques are used. In women who still have their uterus, the procedure is generally performed leaving lateral channels on each side of the vaginal vault to permit uterine drainage. Total colpocleisis is used in women after hysterectomy and consists of a denudation of the vaginal mucosa and subsequent reduction and conical closure of the prolapse. Perineoplasty is performed to reduce the size of the vaginal introitus and prevent recurrence of bulging from the outlet. Women must be expressly counseled that penetrative sexual activity will not be possible after this type of surgery. However, it does not preclude other forms of erotic or sexual activity. Reported success rates with colpocleisis have been high, and rates of subsequent regret after having the procedure are low (Koski et al., 2012; Vij et al., 2014). Colpocleisis has been shown to improve bladder and bowel symptoms in women with a history of significant prolapse (Gutman et al., 2010; Vij et al., 2014).

Urethral caruncle is a protrusion of tissue from the urethra and is seen more commonly in elderly than in younger women. In most cases these are painless and benign. **Unless they are large, they often do not affect voiding function** (Ozkurkcugil et al., 2010). Topical estrogen therapy is useful and often leads to tissue contraction and involution of the caruncle. Surgical excision is not typically necessary. However, if surgery is performed, care must be taken to avoid damage to the external urethral sphincter, which could lead to stress UI.

Urinary Tract Infections and Asymptomatic Bacteriuria

UTI is one of the most common clinical conditions seen in older adults, and particularly in elderly women. **It is important to distinguish between symptomatic UTIs and asymptomatic bacteriuria.** Overtreatment of asymptomatic bacteriuria has been associated with negative outcomes, including potential medication side effects and increased bacterial resistance (Köves et al., 2017). Symptomatic infections require evaluation and treatment, usually with antibiotic therapy. **Urinary cultures are strongly recommended to verify the infection, determine the associated bacterial organism, and identify antibiotic susceptibility or resistance patterns.** Empiric treatment with antibiotics may have to be modified depending on the results of the urine culture and drug susceptibility panels. If older adults have difficulty providing a clean-catch urine specimen, a catheterized urine sample should be obtained to help with accurate diagnosis (Gordon et al., 2013).

Symptoms of acute UTI may include urinary urgency and frequency, cloudy or foul-smelling urine, fever, bladder pain, and dysuria. However, many older adults may not show these symptoms because of alterations in the immunologic or other systems (Arinzon et al., 2012). Instead, **elderly patients may experience what have been called “atypical” symptoms in other populations. These include confusion, agitation, lethargy, and anorexia among others** (Juthani-Mehta et al., 2009). Acute UTIs in older adults can lead to clinically symptomatic delirium (Eriksson et al., 2011). Urine cultures should be checked to determine if an associated UTI is present, and appropriate antibiotic therapy initiated if indicated.

More complex UTIs such as pyelonephritis are often associated with underlying comorbidity, including diabetes, anemia, and urolithiasis (Kang et al., 2008). Antibiotic therapy should be instituted in most cases and should be based on culture and drug susceptibility results. **Urosepsis in elderly patients can be serious, and increased mortality is seen in this population.** Associated factors that increase the risk of mortality from bacteremia in geriatric patients include advanced age (≥85 years), chronic renal disease, severe cognitive impairment, and hypothermia (Rebelo et al., 2011). Hospital-acquired UTIs also appear to be a greater risk for mortality compared with community-acquired infections, at least among older adults in acute hospital settings (Chin et al., 2011). Treatment of these serious infections typically requires directed antibiotic therapy and fluid resuscitation. Fungal UTIs occur more commonly with advanced age, and particularly in patients with reduced immune status, including those with a history of transplant, advanced human immunodeficiency virus (HIV) disease or acquired immunodeficiency syndrome, and those with poorly controlled diabetes. Treatment with antifungal agents such as fluconazole can be effective in many cases (Fraisse et al., 2011). Antibiotic treatment in nursing home settings should be done judiciously based on culture results to help reduce the risk of developing increased antibiotic resistance in this setting (Sundvall et al., 2014).

In contrast, **asymptomatic bacteriuria is very common in older adults and generally does not require therapy. Approximately 10% to 20% of all older women living in the community will have bacteria in their urine on routine analysis, and rates are typically higher in long-term care and other institutional settings** (Varli et al., 2012). Although less common than in women, rates of asymptomatic bacteriuria still approach about 10% in community-dwelling elderly men (Juthani-Mehta, 2007). Asymptomatic bacteriuria has been associated with increased serum and urinary inflammatory cytokines, but this does not necessitate antibiotic therapy (Chang et al., 2012). Dipstick urinalysis can be useful in diagnosis, particularly in long-term care settings, with a goal to correctly differentiate symptomatic UTI and asymptomatic bacteriuria and reduce overuse of antibiotics when not clinically indicated (Bonnal et al., 2008; Sundvall and Gunnarsson, 2009). The AGS has included avoidance of antimicrobial therapy for asymptomatic bacteriuria as one of their original five things to avoid or question as part of the Choosing Wisely campaign (AGS Choosing Wisely Workgroup, 2013).

A variety of clinical factors increase risk of UTIs in older adults. CAUTIs are one of the most prevalent types of infection seen in acute care hospitals and other inpatient settings (Daniels et al., 2014). CIC can reduce infection rates in patients with chronic urinary retention, although one study of elderly stroke survivors did show a trend toward increased infection rates (Stott et al., 2009). However, this association disappeared after controlling for stroke severity. Body mass index has been linked to UTI in older adults with obese and significantly underweight elderly patients having higher rates of infection (Dorner et al., 2010).

Administration of vaginal estrogens can be useful in reducing rates of symptomatic UTIs in elderly women. After menopause, there is loss of the natural acidification of vaginal fluid. This increased alkalinity prevents growth of *Lactobacillus* sp., the natural flora in the vaginal vault. *Lactobacillus* sp. is an important part of the natural host-defense mechanism to prevent UTI. **Addition of topical vaginal estrogens can help reacidify vaginal fluid, which permits growth of *Lactobacillus* sp.** This in turn helps to kill off pathogenic bacteria that cause symptomatic UTI. The medication comes in several different forms, including vaginal creams, vaginal tablets or suppositories, and a small ring-shaped device that releases estrogen continuously over several months. If using creams, a small amount with fingertip application in the vagina is usually sufficient administered three times weekly at bedtime. Vaginal estrogens are generally contraindicated in women with a personal history of either breast or uterine cancer. However, emerging data suggest that women with known estrogen receptor negative (ER−) breast cancers may be able to safely use this type of therapy. The amount of estrogen absorbed systemically is usually low. Patients with this type of history should consult with their oncologist before starting therapy.

The use of cranberry juice or other cranberry supplements is popular with many people as a form of UTI prophylaxis. This works by interaction between fructose and proanthocyanidins in cranberry and bacterial cell walls, which leads to inhibition of adherence to the urothelium. Although many people describe clinical efficacy, results in scientific studies have been mixed. Recent data from a randomized, double-blind, placebo-controlled trial in nursing home residents showed there were reductions in infection rates, but these were limited to those patients with a previous high-rate of infections (Caljouw et al., 2014). The overall cost effectiveness of cranberry therapy also appears to be limited based on observed clinical outcomes and economic analysis, which demonstrated an estimated cost of more than $5200 annually to prevent one clinically significant UTI (van den Hout et al., 2014).

Chronic antibiotic use for UTI prophylaxis should be avoided unless no

other options are available because of an increased risk of development of resistant organisms. The choice of antibiotics is also important. Although it can be useful for short treatment of acute infections, nitrofurantoin should be avoided for chronic prophylaxis because of risks of pulmonary fibrosis and associated complications in older adults. In addition, it should be avoided in those with impaired renal function defined as creatinine clearance (CrCl) less than 30 mL/min (American Geriatrics Society Beers Criteria Update Expert Panel 2015; Leung et al., 2007).

Evaluation and management of UTIs in nursing home and assisted care settings require special consideration. Overuse of antibiotics is very common in these locations, and this may be due to the substantial challenge of correctly diagnosing symptomatic UTIs in older nursing home residents who may have subtle or atypical symptoms (D'Agata et al., 2013; Juthani-Mehta et al., 2007; Kistler et al., 2013). In addition to avoiding treatment of asymptomatic bacteriuria, careful antibiotic selection is important. **Use of antibiograms based on local prevalence of specific organisms can help guide therapy.** Guidelines from professional organizations can also help to reduce overuse of specific antibiotics that may increase the risk of developing drug-resistant infection in given locations (Daneman et al., 2011; Fagan et al., 2012). As with acute care hospitals, data suggest that environmental contamination in nursing homes may increase the risk of some types of infections, including methicillin-resistant *Staphylococcus aureus* (Murphy et al., 2012). Strict hand washing and other infection prevention methods can help to substantially reduce this risk.

However, several studies have recently shown less than 10% of UTIs diagnosed in nursing home settings actually met established surveillance guidelines that include symptoms and culture results (Ryan et al., 2018).

The costs associated with evaluation and treatment of UTIs in the United States are staggering and surpass almost all of the other major genitourinary disorders (Griebling, 2005a, 2005b). This is due to multiple factors including a high incidence and prevalence of UTIs but also excess evaluation and overtreatment of conditions that may not require therapy including asymptomatic bacteriuria. A sizeable volume of clinical care for UTIs is provided in emergency room settings, which exponentially increases associated costs.

Hematuria

Hematuria is a common clinical condition seen in elderly patients,

particularly those on anticoagulants. Patients with gross or persistent microhematuria should undergo clinical evaluation (Davis et al., 2012). The use of anticoagulation is common in older adults, particularly for prevention of stroke in those with atrial fibrillation and other arrhythmias, deep vein thrombosis, and other hematologic disorders. Supratherapeutic anticoagulation, particularly with warfarin, has been associated with an increased risk of developing acute kidney injury (AKI) (Lim and Campbell, 2013).

Genitourinary Trauma

Evaluation and management of genitourinary trauma in elderly patients requires some special considerations. **Compared with younger adults, elderly patients are more likely to experience blunt rather than penetrating traumatic injuries. Underlying comorbidity and clinical conditions associated with the aging process put geriatric patients at higher risk for poor outcomes.** For example, falls are one of the leading causes of traumatic injuries among older adults, with more than 2.3 million emergency room visits for this annually in the United States (CDC, 2010). The rate of genitourinary injuries resulting from falls in geriatric patients is 26.5% compared with 8.4% in younger adults ($P < 0.0001$) (Bjurlin et al., 2011).

The basic principles of management of genitourinary trauma do not differ considerably based solely on age. The decision for conservative versus more aggressive therapy should be based primarily on the nature of the injury. However, careful consideration of associated comorbidity with medical optimization of these other conditions is essential for successful management. For example, **older adults with osteoporosis may be at higher risk for pelvic fracture because of falls compared with those without this associated comorbidity.** Treatment in these patients may require different techniques including greater use of embolization therapy compared with younger or healthier patients (Kimbrell et al., 2004). **Men on androgen deprivation therapy are at higher risk for hip and long bone fractures because of changes in bone mineral density associated with hormonal therapy** (James et al., 2014). Treatment with agents such as alendronate or zoledronic acid may decrease this facture risk in these patients (Campbell et al., 2010; Planas et al., 2009).

Older adults are also more likely to require discharge to either a rehabilitation facility or nursing home (13.6% and 18.5%, respectively) compared with younger adults (8.6% and 3.1%, respectively) after acute management for genitourinary trauma (both, $P < 0.0001$) (Bjurlin et al., 2011). Geriatric trauma is a relatively new scientific field, and additional work will be needed to better identify specific protocols for this population. Early research has shown inclusion of data on chronic comorbidities in geriatric trauma patients may be superior to traditional measures of vital signs and injury pattern alone in decision-making and clinical outcomes (Brooks et al., 2014). In addition, there is interest in creating and validating an index of frailty specific for elderly trauma patients to see if this may influence evaluation, treatment, and outcomes (Joseph et al., 2014).

Genitourinary Malignancies

Almost all of the genitourinary cancers occur with greater incidence and prevalence in geriatric patients compared with their younger counterparts. The one exception is testis cancer, in which lymphoma is the most common histology seen in geriatric men.

Prostate Cancer

The evaluation and treatment of prostate cancer in elderly men differs somewhat from the general population. The US Preventive Services Task Force recommendation does not support routine screening for prostate cancer in any group, although this is highly controversial (Moyer et al., 2012; US Preventive Services Task Force, 2008). **When prostate cancer screening is performed, it is generally recommended that this be discontinued in men once they reach 70 to 75 years of age.** This is because definitive therapy for prostate cancer is typically reserved for men with an estimated remaining life expectancy of 10 or more years (Hoffman et al., 2010). Because the mean life expectancy for men in the United States is approximately 82 to 84 years, most clinicians would argue to limit use of definitive therapy with radical prostatectomy or radiation therapy to those aged 75 years or younger. Interestingly, in survey research, about a third of older adults indicate that they would rather not know either their predicted life expectancy or survival probability (Clarke et al., 2008). This can be problematic in relation to discussions about clinical decisions in this population.

Recent research has examined factors that can be associated with recommendations to stop screening, including prostate-specific antigen (PSA) velocity and genetics, and risk factor group profiles (Tang et al., 2010, 2011). Despite these recommendations, many older men choose to continue screening for various personal reasons (Caire et al., 2010; von Wagner et al., 2013). There is also some variation among practitioners in terms of following these guidelines for discontinuing screening in geriatric men (Bynum et al., 2010; Hudson et al., 2009; Whittle, 2010). **In contrast to routine screening, targeted diagnosis in select patients at risk for prostate cancer can help to guide therapy, even if it is not done with curative intent** (Abdollah et al., 2016; Paterson et al., 2013). This can help in the overall care and management of disease in older men.

There are a number of caveats that must be considered based on the overall clinical situation for each man. The AUA has published guidelines on treatment of clinically localized prostate cancer that include considerations related to overall health, comorbidity, and age (Thompson et al., 2007). The International Society of Geriatric Oncology recently published results of a study indicating importance of including assessment of ADL and IADL function in the care decisions for elderly men with prostate cancer (Droz et al., 2010). The combination of functional status and disease burden combined with predicted longevity and other parameters may help with this complex decision process.

Although prostate cancer in elderly men is often an indolent, slow-growing disease, some have more aggressive cancers (Kunz et al., 2013; Scosyrev et al., 2012). In addition, some studies have shown that elderly men tend to have higher-risk disease (Vatandoust et al., 2018). Various factors may predispose to more advanced prostate cancer in elderly men including a history of hypertriglyceridemia (Hayashi et al., 2012). However, other studies continue to show that most elderly men die of other diseases, including cardiovascular and pulmonary disorders (Jeong et al., 2009; Ketchandji et al., 2009). Multiple risk factors for prostate cancer in elderly men have been identified, including genetics and diet. Recently, an epidemiologic study has identified a potential association between Alzheimer disease and prostate cancer, which may be linked to androgen receptor reactivation resulting from oxidative stress (Lin et al., 2018). There is also evidence linking components of the metabolic syndrome with increased prostate cancer risk in elderly men (Zhang et al., 2015).

Several studies have shown that elderly men who undergo radical prostatectomy can have good clinical outcomes that in many cases are equivalent to those seen in younger men (Greco et al., 2009; Namiki et al., 2010; Pierorazio et al., 2010). However, other studies have demonstrated that elderly men are at higher risk for negative clinical outcomes, including upgrading and upstaging of their disease, greater risk for biochemical recurrence, and surgical complications (Ko et al., 2013; Richstone et al., 2008; Trinh et al., 2012). Radiation therapy is often used in elderly prostate cancer patients because it is considered to be less invasive. It has been associated with acceptable clinical outcomes including health-related quality of life, although as with any treatment there are risks for incontinence and erectile dysfunction among others (Mirza et al., 2011; Namiki et al., 2010). UI can be particularly bothersome in elderly men treated for prostate cancer. This can have substantial negative effects on activity, mood, and quality of life (Kopp et al., 2013; Park et al., 2012). Cryotherapy has been advocated as a possible treatment for elderly men with organ-confined prostate cancer who may not be candidates for more invasive forms of therapy (Dhar et al., 2011).

In elderly men with metastatic prostate cancer, hormonal therapy or chemotherapy may be used to reduce disease progression. Docetaxel has been shown to improve overall survival in early trials (Miyake et al., 2012). **Androgen deprivation therapy can certainly be useful in select patients but is also associated with potential adverse effects, particularly in elderly men.** ADT has been shown to increase the risk of cardiovascular disease, myocardial infarction, and diabetes in elderly men (Keating, 2013). Changes in bone mineral density are associated with increased risk of fractures because of osteoporosis and osteopenia (Shao et al., 2013). These effects can be tempered by use of agents such as alendronate and zoledronic acid (Campbell et al., 2010; Planas et al., 2009). Other negative side effects include decreased libido, gynecomastia, hot flashes, and sexual dysfunction. ADT has also been linked to development of sarcopenia in elderly men (Reis et al., 2009). ADT has been associated with an increased risk for depression and potential risk of suicidality (Chung et al., 2017; Welk et al., 2017; Zhang et al., 2017).

Finally the cost of ADT may be a barrier to ongoing therapy for some patients (Krahn et al., 2011).

Bladder Cancer

Bladder cancer is one of the most common urologic malignancies seen in the geriatric population, and incidence and prevalence increase substantially with advancing age. Because of the long latency of carcinogen exposure, age is one of the most important independent risk factors for development of bladder cancer with a median age at diagnosis of more than 70 years (Shariat et al., 2010b). In general, diagnosis is similar in elderly and younger patients. Diagnosis of bladder cancer is associated with negative effects on overall and health-related quality of life with reductions in physical and mental health domains (Fung et al., 2014). Conversely, increased rates of depression and other psychiatric illness are associated with worse survival outcomes in older adults treated for bladder cancer (Jazzar et al., 2018).

Guidelines have been developed for evaluation and management of bladder cancer, and an audit study showed that these are generally followed (88.8%) in elderly patients (Bolenz et al., 2010). The role of tumor restaging with repeat resection has been demonstrated in elderly patients, although rates have been shown to be low among Medicare beneficiaries (Skolarus et al., 2011). This can be very useful to help identify muscle-invasive disease, which may require different treatment. Interestingly, bacille Calmette-Guérin (BCG) therapy has shown decreased efficacy in elderly patients with non–muscle-invasive bladder cancer compared with younger patients (Margel et al., 2011). This may be due to an age-related decease in the immune system and reduced ability to mount an immune response to therapy in geriatric patients. A recent study examined extending the initial BCG dosing schedule to every other week for more frail older adults and demonstrated improved tolerability with no significant reduction in clinical survival outcomes (Racioppi et al., 2018).

Treatment for muscle-invasive bladder cancer has generally focused on surgical extirpation with radical cystectomy and urinary diversion. From a surgical standpoint, this is one of the most invasive and potentially morbid surgeries done in the field of urology. In addition, many of these patients have substantial underlying comorbidity. For example, the condition is strongly linked to a history of smoking, which can predispose to lung disorders such as chronic obstructive pulmonary disease (COPD) and restrictive airway disease. These increase the risk of anesthetic complications in this already vulnerable population.

Multiple studies have demonstrated that with careful preoperative planning and intraoperative and postoperative management, radical cystectomy can be accomplished safely even in elderly patients (Guillotreau et al., 2012; May et al., 2007). This appears to convey a potential survival advantage in many patients (Tyritzis et al., 2012). However, this must be evaluated within the context of overall health and comorbidity. **Many patients with bladder cancer may die of other competing conditions, and this must be considered when making treatment decisions for elderly patients with muscle-invasive bladder cancer** (Donat et al., 2010; Fisher et al., 2009; Resorlu et al., 2009). Some studies have shown an increased rate of peri- and postoperative complications in elderly patients undergoing radical cystectomy, likely resulting from other chronic disease and functional status (Liberman et al., 2011; Lund et al., 2010). Sarcopenia, a key component of the frailty phenotype, appears to be a predictor of postoperative complications in elderly women undergoing radical cystectomy (Smith et al., 2014). Diminished performance status has been shown to be a negative predictor of outcomes among geriatric patients treated for muscle-invasive bladder cancer (Weizer et al., 2007).

Bladder-sparing therapies with endoscopic resection and adjuvant chemotherapy and/or radiation have been examined (McPherson et al., 2017; Williams et al., 2018). Some studies have shown similar survival rates for more conservative therapy compared with radical cystectomy (Martini et al., 2013). However, overall time in hospital is often greater for those treated with bladder-sparing therapies, and this can have a negative impact on remaining quality of life (Wehrberger et al., 2010). Other data suggest very elderly patients and those with more clinical comorbidity have poorer outcomes in terms of overall and cancer-specific survival (Kohjimoto et al., 2010; Tran et al., 2009). A recent large database study demonstrated trimodal therapy had inferior survival compared with older adults who underwent radical cystectomy (Williams et al., 2018). Radiation therapy has been used mostly for palliation of significant bleeding in patients who are otherwise not suitable surgical candidates (Kouloulias et al., 2013). This therapy appears to be well tolerated in these select patients.

Kidney Cancer

Kidney cancer is often diagnosed as an incidental finding in geriatric patients undergoing abdominal imaging for other conditions. Over the past 30 years, there has been a steady increase of 2% to 3% annually in the incidence of kidney cancer diagnoses (Chow et al., 1999). **Although increased rates of kidney cancer have been seen in all age groups, the largest have been identified in those in the seventh and eighth decades of life** (Katz et al., 1994). In elderly patients with small tumors, surveillance is feasible and may preclude the need for invasive surgery (O'Malley et al., 2010). Advanced age over 75 years has been identified as a risk for more advanced disease, and older adults may need to be watched with greater caution. It is important to consider overall health and comorbidity when making treatment decisions. Use of measures such as the CCI can be useful in this regard and can help identify those who may be at substantially higher risk with treatment (Charlson et al., 1987; O'Connor et al., 2009).

Older adults have been shown to tolerate radical and partial nephrectomy (Sandberg et al., 2014). In general, complication rates do not appear to be substantially influenced by chronologic age but more by comorbidity (Roos et al., 2008; Sun et al., 2012). Laparoscopic and robotic procedures for partial nephrectomy appear to be well tolerated by older adults with similar clinical outcomes and complication rates compared with younger patients (Guzzo et al., 2009; Hillyer et al., 2012; Thomas et al., 2009). However, rates of use of partial nephrectomy in elderly patients still lag behind younger cohorts (Kates et al., 2011). The reasons for this are unclear but may be based on concern over underlying clinical conditions and ability to perform surgery in more frail older adults.

In patients with more advanced disease, cytoreductive nephrectomy has been used successfully in elderly individuals, although some complications including need for transfusion are higher in geriatric patients (Kader et al., 2007; Sun et al., 2012). Subsequent immunotherapy may be difficult in some patients, particularly if they have functional impairments and decreased overall performance status. Radical nephroureterectomy has been described in geriatric patients with upper tract urothelial cancers, although reported cancer-specific survival has been lower in those older than 80 years of age compared with younger patients (Shariat et al., 2010a).

Testis Cancer

Although testis cancer can occur at any age, most germ cell tumors occur in young men between the ages of 15 and 35. **In geriatric men, the most common testicular malignancy is lymphoma** (Shih et al., 2014). **This should be evaluated and treated as a systemic condition because isolated testicular involvement is rare.** When germ cell tumors of the testis do occur in elderly men, evaluation and general treatment principles should follow those of younger men. One important caveat is that doses of chemotherapeutic agents may have to be adjusted based on comorbidity that affects renal, hepatic, or pulmonary function. This highlights the need for a thorough geriatric assessment in these patients. With successful treatment, life expectancy approaches that of other elderly men without testis cancer (Wheater et al., 2011).

Urologic Cancers and Other Health Issues in Older Adults

A diagnosis of cancer can have substantial impacts on overall health, including multiple domains of health-related quality of life. Psychological stress of dealing with a cancer diagnosis and the associated treatments can be substantial for patients and their family and friends (Dräger et al., 2017). Increased research efforts are being targeted at cancer survivors and caregivers to help ease this process.

Sexual Health in Elderly Women and Men

Sexual health is an important part of life for most adults, even at advanced age, and has been linked to improved overall quality of life and an improved sense of well-being (Flynn and Gow, 2015; Lee DM et al., 2016). **Many older adults wish to remain sexually active through their life** (Hyde et al., 2010). Data from the National Survey of Sexual Health and Behavior (NSSHB) in 2009 demonstrated that 20% to 30% of all older adult men and women remained sexually active well into their 80s (Schick et al., 2010). **A common myth is that older adults are not able or interested in participating in sexual activity. Forms of sexual expression may change with time over the lifespan** (Lindau et al., 2007). Lack of a partner is a limiting factor for many older adults. Penetrative sexual activity may become less important for some older adults, and there may be an increased emphasis on intimacy and other types of erotic interaction. Masturbation may become an important form of sexual expression for many older adults.

Comorbidity plays an important role in sexual health for many older adults (Appa et al., 2014). Those with better overall health tend to be more sexually active than those with poorer functional health status (Bach et al., 2013; Lindau and Gavrilova, 2010). **Changes in sexual health may be a sign or symptom of underlying systemic disorders.** Multiple studies have linked obesity, diabetes, cardiovascular disease, and neurologic disorders such as Parkinson disease and stroke to erectile dysfunction in elderly men (Garimella et al., 2013; Justo et al., 2010; Marinkovic and Badlani, 2001; Riedner et al., 2006; Seftel, 2003). Alterations in sex hormones and testis function have been shown to influence erectile function and cardiovascular health in elderly men (Rastrelli et al., 2013). UI and other LUTS can negatively influence sexual health for many older adults (Griebling, 2006; Tannenbaum et al., 2006). Prevalence of UI during sexual activity in women has been shown to be as high as 26% (Visser et al., 2014). **Frailty affects multiple physical and psychosocial domains and has been shown to be linked to worse sexual health status** (Lee et al., 2013). Other physical health issues may influence the ability to engage in sexual activity. Severe arthritis may make some positions for intercourse painful or impossible. Atrophic vaginitis can cause dyspareunia in elderly women. Use of water-based lubricants and vaginal estrogen replacement therapy may be useful in these cases. Many chronic diseases that affect sexual health tend to be underreported and underdiagnosed among older adults. For example, hypogonadism, erectile dysfunction, and osteoporosis are conditions that influence sexuality and overall health that frequently remain undiagnosed in elderly men (Frost et al., 2012).

Sexual health has also been closely linked to mental health in older adults, with higher rates of depression noted in those with erectile or sexual dysfunction (Cheng et al., 2007; Korfage et al., 2009). Satisfactory sexual function has been linked to improved sense of well-being in older men and women (Lee et al., 2016). Cognitive impairment may also negatively influence sexuality in elderly people (Wright and Jenks, 2016). Body image is an important factor with regard to sexual satisfaction and mental health regarding sexuality (Carr et al., 2013). This can be affected by a number of factors including weight, body mass index, and history of prior genitourinary cancer surgery or stoma formation. In longitudinal studies of men, regular sexual activity has been identified as a protective factor in continued sexual health and is associated with lower rates of subsequent erectile dysfunction (Koskimäki et al., 2008).

There are important differences in human sexuality between men and women. In comparison with the plethora of data on evaluation and treatment of erectile dysfunction in men, there has been much less research conducted examining sexual response and health needs in elderly women. **Population-based research does show that many elderly women remain interested in sex and have sexual health care concerns that deserve clinical attention** (Huang et al., 2009; Schick et al., 2010). As with men, comorbid disease such as metabolic syndrome and diabetes can have a negative influence on sexual health (Kim et al., 2011). Older women have been found to place strong emphasis on relationships and psychosocial aspects of sexuality including intimacy (Kim and Jeon, 2013). Improved sexual function has been linked to better self-rated health and life satisfaction in cohort studies of geriatric women (Thompson et al., 2011; Woloski-Wruble et al., 2010). In women who have undergone prior treatment for urologic or gynecologic disease, treatment of the underlying pathology can have a substantial impact on sexual health, and this must be considered in evaluation and treatment (Ratner et al., 2011).

Environmental factors can influence sexual health for many older adults. In some cases, elderly persons may live with extended family or be in situations where privacy for sexual activity may be an issue. **Sexual health in nursing home residents deserves special consideration.** There has been an increased awareness and understanding of this in recent years, and many nursing homes work to accommodate this for residents (Mroczek et al., 2013). This may include allowing couples to live in the same room and share a bed, providing privacy and time free from interruptions or medical care, and offering specific medical and nursing care for sexual health needs. Recent research has worked to develop and validate an assessment instrument specific for sexual health in nursing home residents (Bauer et al., 2014). **In patients with dementia and other cognitive impairment, inappropriate displays of sexual behavior may occur and can be problematic. Ethical considerations include assessment of the broadly defined capacity for a person to make decisions regarding sexual activity** (Wilkins, 2015)**. Specific evaluation and treatment tailored to these issues can be useful in these cases** (Bardell et al., 2011).

Treatment of sexual health problems should be designed to address the needs of each individual patient. This must be done in the context of overall health and comorbidity. For example, elderly men with heart disease may not be candidates for PDE-5 inhibitors if they have a history of chest pain and use nitrates or take medications that contradict use of this treatment. However, in carefully selected patients, oral medications for treatment of ED may be safe and effective (Oelke et al., 2017). Some elderly men may have physical or cognitive impairments that limit the use of other therapies such as penile injections or vacuum erection devices. Surgery with placement of a penile prosthesis may be an option for some patients but could be limited in those who are poor surgical candidates. Some men do well with this, and advanced age alone should not be the deciding factor for selection for surgery (Al-Najar et al., 2009).

Some adults may engage in relatively high-risk sexual behaviors, and this can put them at risk for transmission of sexually transmitted diseases including HIV. Condom use in this age group has been reported to be relatively low overall and may increase risk for some people (Choe et al., 2011; Schick et al., 2010). This generation was never really targeted in public health campaigns about safer sex, and specific counseling about this is warranted. Some health care providers may lack awareness or expertise about geriatric sexuality. **Clinicians need to appreciate their own level of comfort and knowledge in providing sexual health care in the geriatric population and seek additional information or**

consultation with others if needed.

Sexual orientation is an important factor to consider in sexual health care. To date there has been relatively little research on the specific sexual health needs or goals of elderly lesbian, gay, or bisexual persons (Griebling, 2016b). There has recently been increased interest in this area, and a national summit identified research and clinical needs specific to this population in relation to cancer care (Burkhalter et al., 2016). Additional work in this field will help to increase understanding to improve quality of care. Transgender older adults may also have unique urologic needs, including hormonal replacement and care after reconstructive surgery (Gooren and Lips, 2014). Cultural and religious views play an important role in human sexuality and should be considered and respected in the evaluation and treatment of sexual health in the older adult population. **The goal should be to provide sexual health care that is respectful of each patient's needs, desires, and goals of therapy.**

Discharge Planning and Care Coordination

Successful management of geriatric urology patients, particularly those undergoing surgical therapy, requires careful coordination and planning. Within this context, discharge planning is vitally important. **Many older adults admitted to hospital or who undergo surgery will lose independence of at least one of the ADLs at least temporarily. Some may manifest new onset or exacerbation of previously existing complex geriatric syndromes** (Bell et al., 2016). This may necessitate assistance from caregivers or transition to another place for care. A variety of options are available after discharge from the acute care hospital including home health nursing or other care services, inpatient or outpatient rehabilitation, and placement in a skilled care facility. Nearly $40 billion dollars are spent annually on this type of post-discharge care, which represents about 10% of the total Medicare budget (Robinson et al., 2011). Full recovery to pre-hospitalization baseline levels can occur but is less common than some level of continued impairment (Gill et al., 2009).

High-quality communication between acute care discharging hospital staff and receiving staff at long-term care facilities can greatly facilitate these transitions (King et al., 2013). Goals of care must be carefully considered, and needs and abilities of family or other loved ones to assist in the process must be assessed. Cost is an important factor, and options may be determined in part by coverage available to individual patients**. Ideally, discharge planning should begin as**

early as possible when treatment determinations are being made. If the patients are to return to their home in the community, what is the environment like and how will this influence function? Are there stairs in the home and are they able to maneuver them safely? What are the toilet facilities like in the home, and are modifications such as grab bars, a bedside commode, or other accommodations needed? Input from professionals in multiple health care disciplines including urology, nursing, physical and occupational therapy, social services, and others can be extremely helpful. The psychological and emotional needs of the patient and caregivers should also be considered (Farage et al., 2008; Gotoh et al., 2009). Development of UI can be particularly stressful for older adults who may already have substantial other requirements (deVries et al., 2012). Particularly in cases in which care needs are significant or require extensive time, caregiver burden must be considered (Tamanini et al., 2011).

Elder Mistreatment

Mistreatment of older adults is an unfortunate but common problem that requires vigilance and a high index of suspicion for optimal diagnosis and intervention. **Screening for elder mistreatment is a responsibility of all health care providers.** In the United States and many other countries, health care providers are mandatory reporters for suspected abuse or neglect. Clinicians who report suspected elder mistreatment in good faith are typically protected from liability or retaliation. Increasingly, urologists and other urologic health care providers are seeing older adults on an ongoing basis for treatment of chronic conditions. Therefore these clinicians may be in an excellent position to identify potential abuse and neglect among elderly patients. **There are a variety of types of elderly mistreatment that must be considered including physical abuse, emotion and psychological abuse, sexual abuse, financial exploitation, and neglect by caregivers or self-neglect.**

A careful history and physical examination is essential to diagnose and document suspected elder mistreatment. Ideally, the interview and examination should be conducted privately with the older adult, but this can be difficult particularly if the patient has impairments in cognition, vision, speech, or hearing. **Providers need to be alert to potential signs of abuse or neglect,** including overall appearance, poor hygiene, distractions, or nervous interactions particularly with accompanying caregivers, or social withdrawal and avoidance of questions. Other physical signs of abuse and neglect include bruises, abrasions or lacerations, or physical findings that are out of proportion to the described mechanism of injury. A careful genitourinary and pelvic examination should be performed in cases of suspected sexual abuse, and screening for sexually transmitted infections should be considered.

Identification of sexual mistreatment of older adults is particularly in the realm of urologic care. It is defined by the National Center on Elder Abuse as "nonconsensual sexual contact of any kind" (Department of Health and Human Services, 2014). Clinicians should be alert for signs and symptoms of sexual abuse, including genital lacerations or other injuries, unusual or unexpected infection patterns including sexually transmitted infections, and avoidance behavior or fear on the part of the patient. Changes from prior observed behavior may be particularly noticeable if the clinician has been following an older adult patient longitudinally over time.

UI has been identified as a risk factor for increased rates of psychosocial abuse against elderly people (Garre-Olmo et al., 2009). Increased rates were also noted in those with depression and social isolation, conditions that are often associated with incontinence. **UI has been identified as a risk factor for neglect of older adults by their caregivers** (Heath et al., 2005). Self-neglect by older adults is also a common but frequently undiagnosed problem. **Increased rates of self-neglect have been associated with higher levels of self-reported disability and impairments in baseline physical function** (Dong et al., 2009). The question of whether successful treatment of UI among older adult patients will help prevent or reduce rates of associated abuse and neglect deserves additional research attention.

End-of-Life Care and Urology

Palliative and end-of-life care is an important part of urologic health for many older adults. Some of the urologic malignancies may progress to a point where palliative care is appropriate. **When cure of the condition is no longer possible, treatment can shift to a palliative care mode. This does not mean that all treatment is withdrawn or that it is less focused or intense than curative therapy. Indeed, aggressive symptom management is one of the hallmark goals of palliative care** for most patients. Urologists and other urologic health care providers play an key role in the care of patients at the end of life who have genitourinary disorders (Sinclair et al., 2015).

Important aspects of high-quality palliative care include pain and symptom management, realization of personal goals for the patient and family, and coordination of care (Agar et al., 2009). Surgical therapy may play a role in select cases in which cytoreductive therapy for a large tumor burden, or removal of tumor for intractable bleeding or pain may help to relieve symptoms. In some cases, urinary or bowel diversion may be indicated for this purpose. Selective radiation therapy for painful bone metastases may be useful. Treatment is highly selective and tailored specifically to the needs of each individual patient. Integrated health care delivery models that include providers from multiple disciplines is feasible and can help to improve the delivery of care in these circumstances (Bergman et al., 2016). Among older adults in assisted living facilities, **use of hospice services has been shown to reduce need for nursing home or other institutional placement** (Dobbs et al., 2012). This can allow patients to remain living at home as long as possible and can increase quality-of-life outcomes in this setting. Consultation with trained, dedicated palliative care specialists can be extremely helpful in providing necessary care for older adults near the end of life.

Summary

The aging process can have substantial effects on the genitourinary system in men and women. Care for older adult patients must be tailored to their specific requirements based on a careful assessment and understanding of overall health and comorbid conditions. **Many clinical conditions seen in the specialty of urology occur with greater incidence and prevalence in elderly patients. In some ways, this makes urology, by definition, a "geriatric specialty."** Some facets of urologic care differ significantly between elderly and younger patients. **Clinical principles of geriatrics are not always intuitive, and the body of evidence related to care for elderly patients is growing rapidly.** Additional research and education on these topics will help enhance our ability to provide high-quality care for the older adults whom we serve.

Key Points

- Multiple biologic processes contribute to the phenomenon of normal human aging.
- Aging affects the structure and function of all organ systems, including the genitourinary system.
- The geriatric population is growing at an extremely rapid pace in the United States and in most developed countries worldwide.
- In addition to considering overall health status, functional assessment in geriatric patients includes evaluation of ADLs, IADLs, mobility, cognition, and other health domains.
- Increased comorbidity and decreased functional reserve capacity are common with aging and strongly influence clinical outcomes.
- Comorbidity and changes in functional status tend to be stronger predictors of clinical outcomes in older adults than chronologic age.
- Careful optimization of medical conditions before surgery or other treatment may help improve clinical outcomes and reduce complications in geriatric urology patients.
- Geriatric syndromes are complex, multifactorial conditions that can

negatively affect elderly patients. Examples include frailty, falls, pressure ulcers, polypharmacy, delirium, and urinary incontinence.

- Established urinary incontinence is associated with substantial negative effects in elderly patients, including limitation of activities, depression, and social isolation. Evaluation and treatment plans should be individualized and can help improve or resolve symptoms in many cases.
- Transient urinary incontinence is common in older adult patients and can be caused by many different factors. Successful treatment of the underlying condition will often help to improve or resolve the incontinence.
- Lower urinary tract and bowel dysfunction including BOO, underactive bladder, urinary retention, nocturia, and fecal incontinence are common in geriatric patients.
- POP is common among elderly women and can be successfully treated using either surgical or nonsurgical methods.
- Asymptomatic bacteriuria in geriatric patients does not typically require antibiotic therapy and must be differentiated from symptomatic UTIs.
- Most genitourinary malignancies have higher incidence and prevalence with advancing age.
- Sexuality remains an important part of overall and health-related quality of life for most older adults. Symptoms of sexual dysfunction may be signs of other underlying comorbidity such as heart disease, diabetes, or neurologic conditions.
- Urologists and urologic health care providers can play a key role in identifying elder mistreatment and neglect and are considered mandatory reporters in most locales.
- High-quality palliative and end-of-life care is an important part of geriatric urology practice.
- Patient-centered care is a central focus in geriatrics, and clinical evaluation and treatment should be tailored to meet the needs and goals of each individual, family, and caregiver.

Urinary Tract Fistulae

Dirk J.M.K. De Ridder MD, PhD, FEBU, Tamsin Greenwell MD, PhD

A fistula is an abnormal or surgically made passage between a hollow or tubular organ and the body surface, or between two hollow or tubular organs. **Although most fistulae in patients in the industrialized world are iatrogenic, they may also occur as a result of congenital anomalies, malignancy, inflammation and infection, radiation therapy, iatrogenic (surgical) or external tissue trauma, ischemia, parturition, and a variety of other processes. The continuous leakage of urine and/or fecal material can have a devastating effect on the quality of life of the patient. Except for a palliative setting, the active treatment of fistulae is always warranted.** Although some types of urinary fistulae heal with conservative management, surgery is usually necessary for a definitive repair. Repair and reconstruction of urinary fistulae are sometimes complex. These should be approached on a case-by-case basis, because repair may involve some innovative and even improvisational maneuvers in the operating room. The surgeon should be familiar with a variety of approaches and techniques, because one approach will not be optimal for all patients with a given type of urinary fistula.

General Considerations

Prevention of Fistula

In the developed world the increasing frequency of gynecologic surgery as well as pelvic radiation, forgotten vaginal foreign bodies, or uninhibited cancer growth are the modern causes for vesicovaginal fistulae (VVF) in elderly patients (Hampel et al., 2015). Careful planning and execution of gynecologic or cancer surgery and/or radiotherapy reduce the risk of iatrogenic fistula formation, although there is little research on the impact of preventive measures on this type of fistulae. Even in stage IV cervical cancer, treated with radiotherapy, clear risk factors could not be established (Biewenga et al., 2010).

In the developing world poor perinatal care and the lack of timely cesarean sections for women with an increased risk for obstetric fistula (OF) formation are the main causes in some regions of Africa, Asia, and South America. The risk factors for obstructed labor are well known: illiteracy, low economic status, and short stature (<150 cm) (Kasamba et al., 2013; Tebeu et al., 2012). Recently an increase in obstetric fistulae has been noted in the UK (Hilton, 2016). The finding of a persistent fistula after presumably definitive treatment may suggest the existence of other contributing host factors, such as malignancy, nutritional issues, the possibility of an unrecognized foreign body, tissue ischemia, or surgical factors such as inadequate postoperative urinary drainage, persistent distal urinary obstruction, or technical problems with the surgery (Arrowsmith et al., 1996; Malik et al., 2018).

Preparation and Optimization of Patient

Prevention of urinary fistulae is, of course, paramount; however, nutrition, infection, and malignancy are important considerations not only when assessing a patient for the risk of creation of a fistula during any given intervention but also during an evaluation for the repair of an existing urinary fistula. Although the majority of urinary fistulae in the industrialized world occur in healthy, well-nourished individuals, a nutritional assessment may be an important factor in some patients with fistulae, such as those patients with malignancies. Ensuring adequate nutrition is integral to surgical healing in general but is especially important in the setting of a urinary fistula. Not uncommonly, the catabolic processes contributing to the lack of healing, which may have been a contributing factor in the initial fistula formation, are often ongoing. This is especially relevant in fistulae related to radiation therapy or in debilitated patients.

Medicolegal Aspects

Acquired urinary fistulae in the industrialized world are almost universally unexpected and may result in a great deal of inconvenience, discomfort, and physical disability for the affected individual. They are most often acquired as a result of a medical or surgical intervention for an unrelated problem, and, consequently, considerable emotional and psychological distress often accompany the diagnosis and subsequent treatment. Often medicolegal issues occur with a high risk for litigation (Thomas and Williams, 2000). Nevertheless, minimizing patient discomfort, maintaining a positive and honest patient-physician relationship while providing constant reassurance, and, finally, and perhaps most important, pursuing expeditious and successful treatment of the fistula most often result in a mutually satisfying long-term outcome.

Notably, after the initial early diagnosis of a urinary fistula, which results in external urinary leakage, immediate management or control of the urinary leakage is vital. Addressing this quickly will reduce skin breakdown and related complications, as well as alleviate much of the psychological distress. The judicious use of catheters, pads, skin care, and odor control products and appliances can be very helpful in this regard. These simple measures can often deflect the anger of an otherwise very disaffected patient, thereby reducing the potential for further aggravating an already difficult medical and, possibly, litigious situation.

The principles of repair of urinary fistulae are outlined in Box 129.1 and can be applied to almost any type of fistula involving the urinary tract.

Box 129.1

Principles of Urinary Fistula Management

Ensure adequate nutrition.
Eliminate infection.
Achieve unobstructed urinary drainage and/or stenting.

Remove or bypass distal urinary obstruction.
Beware of malignant cause of fistula.

Principles of surgical management of urinary fistulae are outlined in Box 129.2.

Box 129.2

Principles of Surgical Repair of Urinary Fistulae

Adequate exposure of the fistula tract with debridement of devitalized and ischemic tissue
Removal of involved foreign bodies or synthetic materials from region of fistula, if applicable
Careful dissection and/or anatomic separation of the involved organ cavities
Watertight closure
Use of well-vascularized, healthy tissue flaps for repair (atraumatic handling of tissue)
Multiple-layer closure
Tension-free, non-overlapping suture lines
Adequate urinary tract drainage and/or stenting after repair
Treatment and prevention of infection (appropriate use of antimicrobials)
Maintenance of hemostasis

Key Points: Presentation

- Urinary fistulae are often associated with considerable physical and psychological distress for the patient and can have medicolegal consequences.
- Nutrition, infection, malignancy, urinary obstruction, and the presence of a foreign body are important factors to consider in the initial approach to urinary fistula and in those patients in whom primary therapy has failed.

Vesicovaginal Fistulae

Vesicovaginal fistula (VVF) is the most common acquired fistula of the urinary tract (Gerber and Schoenberg, 1993) **and has been known since ancient times** (Fig. 129.1).

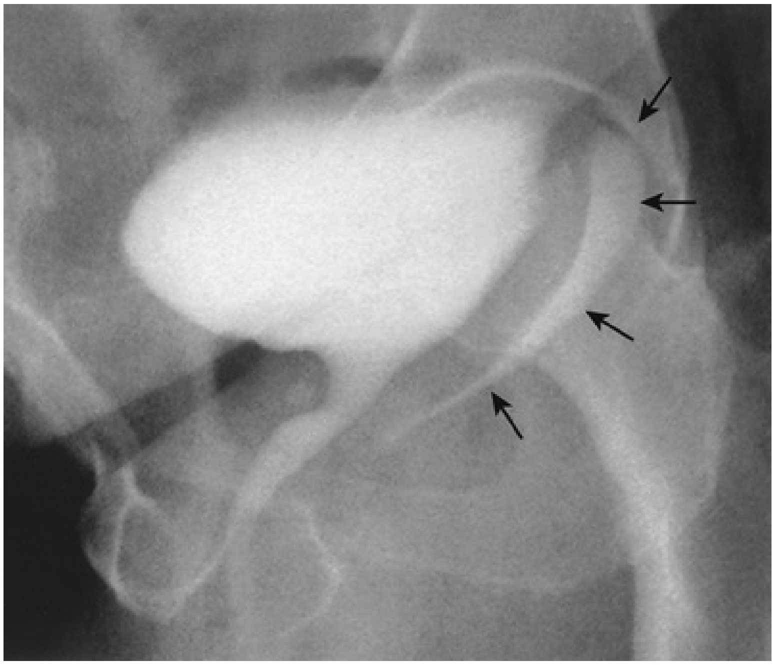

FIG. 129.1 Voiding cystourethrogram demonstrates filling of the vagina *(arrows)* with voiding as a result of a posthysterectomy vesicovaginal fistula.

The first surgical repair was described in 1663 by Hendrik von Roonhuyse denuding the fistula margins and then approximating them with sharpened stiff swan quills (Margolis and Mercer, 1994). Johann Fatio is generally credited with the first successful VVF repair, in 1675, using von Roonhuyse's technique (Falk and Tancer, 1954). In 1838, using leaden sutures, John Peter Mettauer was the first US surgeon to claim a successful VVF closure (Kight, 1967). In 1852 James Marion Sims published his surgical series describing his method of surgical treatment of VVF using silver wire in a transvaginal approach (Sims, 1852). He achieved success at his 30th attempt. The technique was subsequently modified as a partial colpocleisis by Latzko (1942) and the more commonly used dissection and repair in layers or “flap-splitting” technique (variously attributed to Hayward, Collis, and Lawson Tait) (Wall, 2005). **Sims remains the subject of considerable debate regarding his ethics,** because it is unknown whether the patients in his surgical series were willing and consenting participants (all were African-American slaves in pre–Civil War America) (Sur et al., 2017). **The first successful transabdominal approach to VVF repair was reported by Trendelenburg in 1888,** and the concept of **an interpositional flap was first proposed and reported in 1928 by Martius,** who used a labial fat pad.

Etiology and Prevalence

The cause of VVF differs in various parts of the world. In the developing world, VVF is the most common fistula (>75%) and occurs mainly from obstetric complications. As resources increase within these countries, the number of obstetric fistulae seems to decrease, but those of iatrogenic fistulae seem to increase (Tebeu et al., 2012; Wright et al., 2016). **In the industrialized world, the most common cause (>75%) of VVF is injury to the bladder at the time of gynecologic, urologic, or other pelvic surgery** (De Ridder, 2011; Ozdemir et al., 2011; Pal et al., 2016; Tancer, 1992).

Obstetric Fistulae

Epidemiologic studies on obstetric fistulae (OF) are inadequate (De Ridder et al., 2017). A recent systematic review by Adler et al. (2013) found 19 studies that could be evaluated. The studies included data from West Africa, Bangladesh, Turkey, Jordan, Ethiopia, Egypt, and India. The number of new fistulae ranged from 0.09 per 1000 recently pregnant women in community-based studies to 0.66 per 1000 pregnancies in hospital-based studies. Cowgill et al. (2015) performed another systematic review, also looking at the association of stillbirth (SB) and fistulae. They included 62 studies. Incidence estimates ranged from 0 to 4.09 OF cases per 1000 deliveries, whereas prevalence estimates were judged more prone to bias and ranged from 0 to 81.0 of cases per 1000 women. Reported frequency of SB associated with OF ranged from 32.3% to 100%, with estimates from the largest studies around 92%. The major risk factors for both appear to be age at first marriage, short stature, pregnancy with a male child rather than a female child, failure to attend antenatal care, low socioeconomic status, low social class, lack of employment, and illiteracy. Misconceptions on the cause of persist, mostly in rural areas and mostly in men.

The consequences of obstetric fistula include divorce (16%–92%), social isolation, worsening poverty, malnutrition, sexual dysfunction, mental illness (including anxiety/depression), insomnia, general ill health, and thoughts of worthlessness and suicide (Farid et al., 2013; Imoto et al., 2015).

OF most commonly occurs as a result of prolonged obstructed labor resulting from cephalopelvic disproportion, with resulting pressure necrosis to the anterior vaginal wall, bladder, bladder neck, and proximal urethra from the baby (Fig. 129.2; Arrowsmith et al., 1996). **The constellation of problems resulting from obstructed labor is not limited to VVF and has been termed the *obstructed labor injury complex;* it includes varying degrees of each of the following: urethral loss, stress incontinence, hydroureteronephrosis, renal failure, rectovaginal fistula, rectal atresia, anal sphincter incompetence, cervical destruction, amenorrhea, pelvic inflammatory disease, secondary infertility, vaginal stenosis, osteitis pubis, and foot drop.**

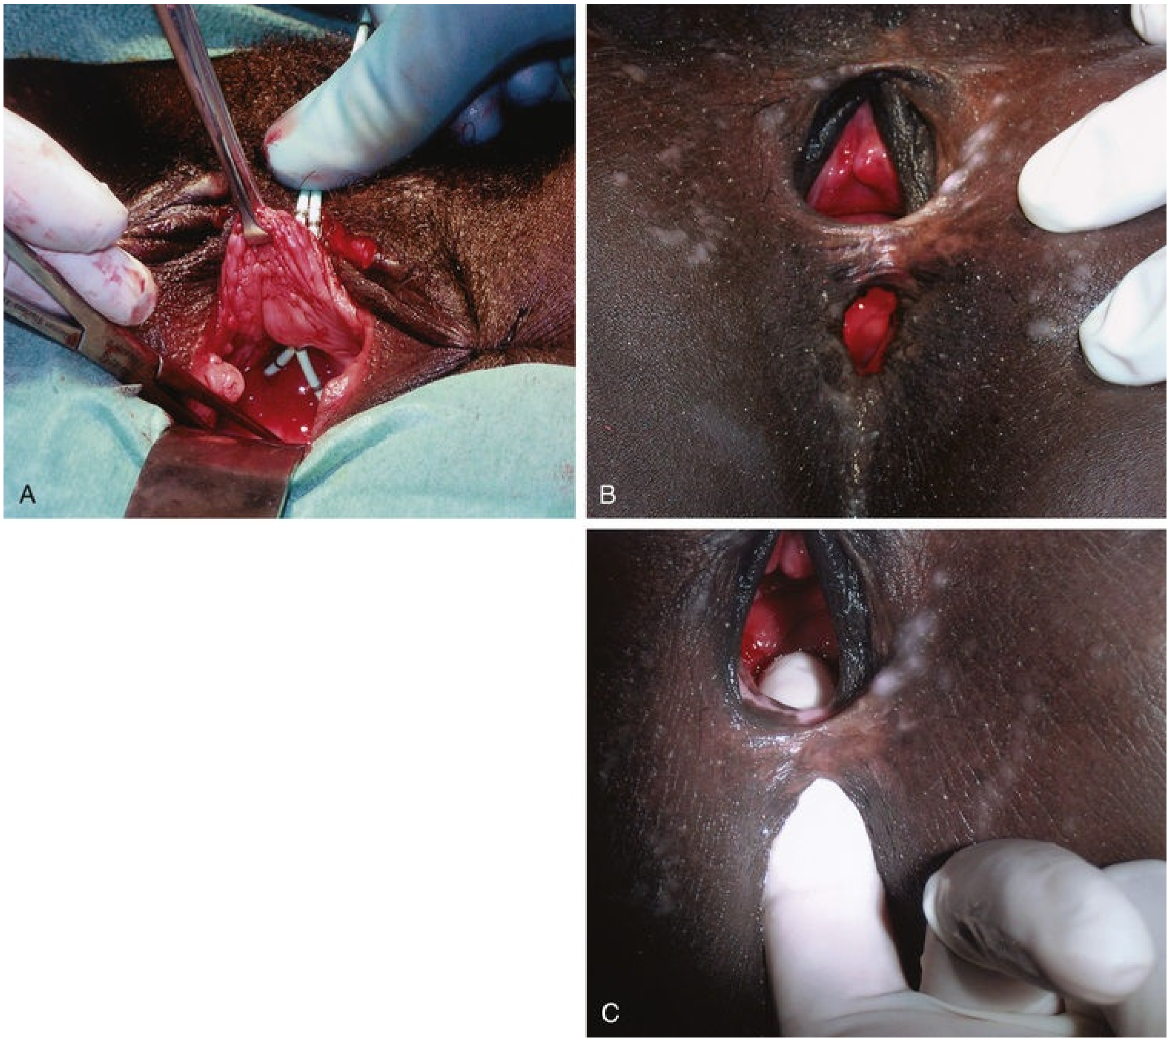

FIG. 129.2 Vesicovaginal fistula (VVF) secondary to obstructed labor. (A) Note the complete loss of the proximal urethra and bladder neck. The ureteral catheters have been passed through the urethra and delineate the ureteric orifices before repair. (B) Large VVF and rectovaginal fistula caused by obstructed labor. (C) Same patient as in B. Digital examination confirms rectovaginal and vesicovaginal fistulae in this patient. (A to C, Courtesy Mark Morgan, MD, Department of Obstetrics and Gynecology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

OF tend to be larger and located distally in the vagina and may involve large portions of the bladder neck and proximal urethra. Even in experienced hands, these VVF are often very difficult to repair because of the extensive soft-tissue loss, as well as the ischemia and fibrosis of adjacent tissues (Arrowsmith, 1994; Arrowsmith et al., 2013; De Ridder, 2011; Kayondo et al., 2011). OF are devastating injuries in the developing world, with significant socioeconomic ramifications (Wall et al., 2004). The affected individuals, commonly young teens, are often ostracized and shunned by family and friends and become permanent outcasts in society.

There are few detailed reports documenting these women's obstructed labors. The time of onset of labor is rarely recorded, and reports from delivery locations may disregard the fact that the woman has labored at home for days before attending the delivery location. The reason for the woman not receiving help rarely differentiates between the absence of health-seeking behavior and the lack of services. A recent study looked at the pathway these patients followed. The mean duration of the fistula was 4 years, and the entire care process took up to 2.7 years, of which 7 months were spent at the repair center (Maulet et al., 2013, 2015).

Misuse of family planning, intercourse during the menstruation, curses by relatives, and sexually transmitted diseases (STDs) are still erroneously seen as potential causes of OF (Kasamba et al., 2013). Education programs should be directed against these misconceptions. Health system causes such as poor quality obstetric care, staff unaccountability, late referral, and poor nursing standards are prevalent in sub-Saharan Africa and rural areas of Pakistan and other parts of Asia (Jokhio et al., 2014; Mselle and Kohi, 2015; Mwini-Nyaledzigbor et al., 2013).

With improvements in the delivery of prenatal care in some areas of the developing world, it appears that the incidence of VVF from obstetric causes may be decreasing as a subset of all VVF, with a proportional increase in the rate of iatrogenic gynecologic fistulae approaching that seen in industrialized nations (Malik et al., 2017; Venkatramani et al., 2014; Wright et al., 2016). Another important cause of VVF in some parts of the world is traditional folk treatments such as “gishiri or guriya cutting,” which may account for up to 13% of VVFs in some series (Ampofo et al., 1990; Ouedraogo et al., 2018b; Tahzib, 1985). This ritual practice involves using a knife to incise the anterior vagina as a treatment for a variety of conditions, including infertility, dyspareunia, dysuria, and back pain.

Iatrogenic Fistulae

Surgical injury to the lower urinary tract most commonly occurs in the setting of hysterectomy (Fig. 129.3). The most common causes of VVF as a consequence of surgery, in developed countries is an injury to the urinary tract during hysterectomy for benign conditions (60%–75%), followed by hysterectomy for malignant conditions (30%), cesarean section (6%), and obstetric injuries (1%) (Hadzi-Djokic et al., 2009; Tancer, 1992). The remainder are related to general surgical procedures in the pelvis, anterior colporrhaphy or cystocele repair, anti-incontinence surgery, or other urologic procedures. Overall, the risk of pelvic organ fistula after hysterectomy has been reported to be between 0.1% and 4% (Forsgren and Altman, 2010). It is important to recognize that most urinary tract injuries do not result in a fistula.

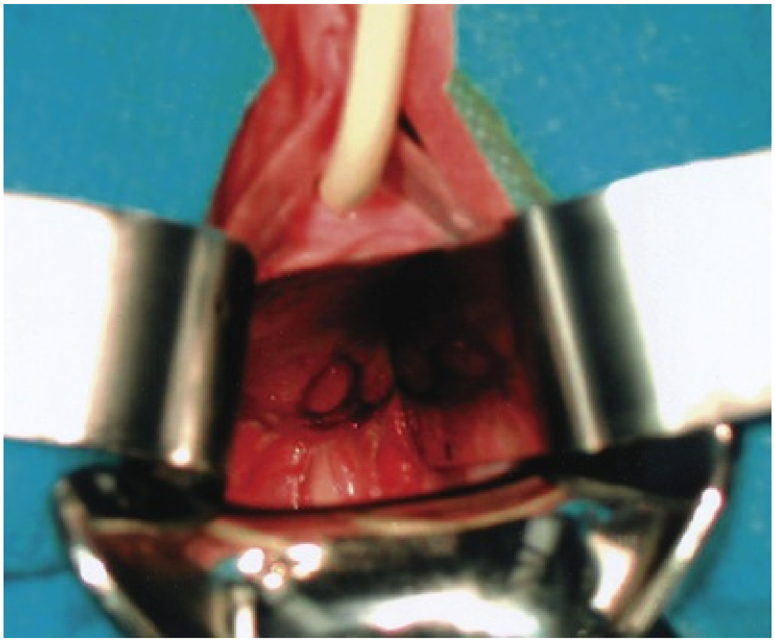

FIG. 129.3 Posthysterectomy vesicovaginal fistula (VVF). Retraction with a weighted speculum and Heaney right-angled retractors to provide lateral retraction are needed to visualize this posthysterectomy VVF in a nulliparous woman.

The prevalence of genitourinary (GU) injury and fistulae vary slightly from center to center. In one US retrospective study from the Mayo clinic, gynecologic surgery was responsible for 82% of the fistulas, obstetric procedures for 8%, and various forms of irradiation for 6%, and trauma or fulguration for 4%. The majority of fistulae followed treatment for benign conditions (Lee et al., 1988). The relative proportions of the types of urinary fistula have changed with urethral fistulae having increased, whereas ureteral, bladder and/or urethral fistulae have decreased.

At the Zekai Tahir Burak center in Turkey, 25,998 gynecologic and obstetric operations were performed over a 3-year period. The bladder was the most frequently injured organ. Urinary tract injury rates were reported to be 0.49% for the bladder and 0.24% for the ureter in gynecologic operations, and 0.18% for the bladder and 0.01% for the ureter in obstetric operations (Ozdemir et al., 2011). The use of vaginal mesh for prolapse repair may also result in VVF (Amundsen et al., 2003; Blaivas and Mekel, 2014; Kasyan et al., 2014; Mishra et al., 2016; Ridgeway et al., 2008). **Posthysterectomy VVFs are thought to result most commonly from an incidental unrecognized iatrogenic cystotomy near the vaginal cuff** (Kursh et al., 1988). If unrecognized intraoperatively, a pelvic urinoma may develop and ultimately drain out through the vaginal cuff. Ongoing urinary drainage along this tract results in a fistula. **Other potential mechanisms for posthysterectomy VVF include tissue necrosis from cautery, a suture placed through the bladder and vaginal wall during closure of the vaginal cuff, or an attempt to control pelvic bleeding by suture ligature.** Tissue ischemia and then necrosis promote fibrosis and induration, finally resulting in an epithelial or mucosal lining of the tract and the development of a fistula tract. It is likely that factors other than an isolated suture placed through the bladder and vagina are necessary for posthysterectomy VVF formation because, at least in an animal model, deliberate suture fixation of the bladder to the vagina does not invariably result in VVF in the absence of infection, urinary extravasation, or other complicating factors (Meeks et al., 1997).

The degree of bladder injury appears to be a major factor in iatrogenic fistula formation. In one study, 1317 benign hysterectomies were reviewed (46% abdominal, 48% vaginal, and 6% laparoscopically assisted vaginal) with reference to risk factors for VVF after intraoperative injury to the urinary tract. In all, 34 cystotomies occurred with 4 (11.7%) developing into a VVF. Patients who developed a VVF were more likely to have a large cystotomy and these individuals trended toward greater tobacco use, larger uterine size, and more operative blood loss (Duong et al., 2009). In another study involving 3076 vaginal hysterectomies with or without additional gynecologic procedures, 1 ureteral injury and 54 bladder lacerations were noted, yielding a total of 4 VVF. The bladder lacerations occurred during the hysterectomy portion of the surgery in 61% of cases and during the additional procedures in 39% (Mathevet et al., 2001). Iatrogenic fistula also in developing countries. Raassen et al. (2014) found 805 iatrogenic fistula in a series of 5959 (13.5%) patients in 11 countries. Most fistulae occurred as a consequence of caesarean section, surgical intervention, or hysterectomy for ruptured uterus (Raassen et al., 2014; Roberto Martinez et al., 2007).

The rate of urogenital fistulae associated with simple abdominal hysterectomy for benign disease is often described as being approximately 1 in 1000. In a national study from Sweden the rate of women undergoing any fistula surgery was reported as 0.26% in women having had a hysterectomy compared with 0.0007% in those not exposed to hysterectomy, with the "number needed to harm" being estimated at 5700 (Forsgren et al., 2009). From Finland the rate of vesicovaginal fistula was reported to be 1 in 1250 after all hysterectomies, 1 in 455 after laparoscopic, 1 in 1000 after total abdominal, and 1 in 5000 after vaginal hysterectomy (Harkki-Siren et al., 1998). The publicly available tables from the national hospital database in England give similar figures of 1 in 600 after total abdominal hysterectomy, and 1 in 5000 after vaginal hysterectomy (Herbert et al., 2017; Hilton, 2011). More detailed longitudinal analysis of patient-level information from the same data set suggests a rate of 1 in 788 for all types of hysterectomy, 1 in 540 for abdominal hysterectomy for benign disease, 1 in 896 after vaginal hysterectomy for benign disease (excluding prolapse), and 1 in 3861 after vaginal hysterectomy for prolapse (Hilton and Cromwell, 2012).

Other causes of VVF include urologic or gynecologic instrumentation, including percutaneous procedures (Armenakas et al., 2004; Pruthi et al., 2000); retroperitoneal, vascular, or pelvic surgery; infectious and inflammatory diseases such as tuberculosis (TB) (Borjas and Rodriguez Diaz, 1949) or other infections (Starownik et al., 2013); congenital VVF (Zeineddine et al., 2014); sexual trauma (Friedman et al., 2017; Roy et al., 2002); vaginal laser procedures (Nwabineli and Davis, 1992); and external violence (Box 129.3).

Box 129.3

Cause of Vesicovaginal Fistulae

- Traumatic
    - Postsurgical
    - Abdominal hysterectomy
    - Vaginal hysterectomy
    - Anti-incontinence surgery
    - Anterior vaginal wall prolapse surgery (e.g., colporrhaphy)
    - Vaginal biopsy
    - Bladder biopsy, endoscopic resection, laser therapy
    - Other pelvic surgery (e.g., vascular, rectal)
    - External trauma (e.g., penetrating, pelvic fracture, sexual)
- Radiation therapy
- Advanced pelvic malignancy
- Infectious or inflammatory cause
- Foreign body
- Obstetric
    - Obstructed labor
    - Forceps laceration
    - Uterine rupture
    - Cesarean section injury to bladder
- Congenital

Foreign bodies such as pessaries, sex toys, herbs, and cups can be also be a cause of VVF (Adaji et al., 2013; Bansal et al., 2016, Birge et al., 2016; Donaldson et al., 2014; Gauta, 2017; Paul et al., 2013; Penrose et al., 2014; Powers et al., 2008). Often their presentation is delayed (up to 15 months). Ketamine abuse can lead to not only severe changes in the bladder wall structure but also fistula formation, as was shown in 14.8% of 27 patients undergoing a computed tomography (CT) urography (Huang et al., 2014).

Intraoperative Risk Factors for Iatrogenic Vesicovaginal Fistulae

Clearly, intraoperative injury to the urinary bladder is a primary risk factor for subsequent development of a postoperative VVF. Other risk factors for postoperative VVF formation include prior uterine surgery (cesarean section), endometriosis, infection, diabetes, arteriosclerosis, pelvic inflammatory disease, obesity, and prior radiation therapy (Hilton and

Cromwell, 2012; Likic et al., 2008, Raassen et al., 2014). **The American Association for the Surgery of Trauma (AAST) grade of the bladder trauma is the strongest predictor of subsequent VVF formation.** Two of 3 patients developing a VVF had a grade V injury, compared with only 1 of 48 who did not develop a VVF. A grade V bladder injury as defined by the AAST involves injury to the trigone. It postulated that the proximity of the injury to the vaginal cuff serves as an avenue for VVF formation because the site of the bladder injury comes in direct contact with the healing cuff (Duong et al., 2011). **The operative approach to hysterectomy is an important factor, because bladder injuries are at least three times more common during abdominal hysterectomy compared with vaginal hysterectomy.** Hilton calculated the risk for fistula formation in radical hysterectomy for cervical cancer to be 1 of 87, whereas in vaginal hysterectomy for prolapse, the risk was only 1 of 3861 (Hilton and Cromwell, 2012). Intraoperative recognition and repair of bladder injury are paramount in prevention of VVF; however, despite intraoperative repair, VVF may still occur in a substantial number of patients. In 1969 Hutch emphasized five factors in the prevention of VVF during gynecologic surgery: (1) immediate detection of bladder injury using vital dyes if necessary; (2) watertight closure of the bladder; (3) satisfactory extravesical drain placement; (4) avoidance of a vaginal incision, if possible, after recognition of the bladder injury; and (5) prolonged, uninterrupted postoperative bladder drainage (Hutch and Noll, 1970).

It has been suggested that patients with severe abdominal pain, distention, paralytic ileus, hematuria, or symptoms of severe irritability of the bladder after abdominal hysterectomy be investigated early for a possible bladder injury (Kursh et al., 1988).

Evaluation and Diagnosis

VVF must be distinguished from other causes, including urinary incontinence, stress (urethral) incontinence, urgency (bladder) incontinence, and overflow incontinence, as well as ureterovaginal fistula.

Presentation

The most common complaint in patients with VVF is constant urinary drainage from the vagina. The amount of urinary leakage can vary considerably from patient to patient and may be proportional to the size of the fistula tract. Patients may void a variable amount, depending on the position and size of the fistula, and the volume of urinary leakage. For example, when a large VVF is present, patients may not void at all and simply have continuous leakage of urine into the vagina. Small, pinpoint fistulae may cause intermittent wetness, which is positional in nature. In the supine position, when sleeping, the amount of leakage reported by the patient may be minimal, but on rising to a seated or standing position the amount of leakage may increase precipitously. Patients may also report recurrent cystitis, perineal skin irritation from constant wetness, vaginal fungal infections, or rarely pelvic pain. In fact, **pain is an uncommon finding in patients with VVF unless there is considerable skin irritation or the VVF occurred as a result of radiation therapy.**

VVF after hysterectomy or other surgical procedures may manifest after removal of the urethral catheter, or the VVF may be seen 1 to 3 weeks later with urinary drainage from the vagina. It may be possible to identify some patients at high risk for VVF in the immediate postoperative period. Kursh et al. (1988) noted that patients who developed VVF after hysterectomy more commonly had postoperative ileus, hematuria, bladder irritability, and elevated white blood cell count compared with a cohort of patients who did not develop VVF. Occasionally posthysterectomy VVF may go undiagnosed for an extended period of time because postoperative clear or serosanguineous vaginal discharge is often attributed to the surgery.

As noted previously, VVF resulting from radiation therapy may not manifest for months to years after completion of radiation.

Physical Examination

A pelvic examination with a speculum should always be performed in the evaluation of VVF. The vaginal speculum examination usually provides a precise assessment of VVF including the location, size, and number of fistulae. Identification can be easier with a dye in the bladder. Vaginoscopy has been suggested as an adjunct measure, in some cases, using a modified endoscope or flexible cystoscope to visualize precisely the fistula tract (Andreoni et al., 2003). **Most commonly, VVFs after hysterectomy are located along the anterior vaginal wall at the level of the vaginal cuff** (Fig. 129.4)**. A visual and manual assessment of inflammation surrounding the fistula is necessary, because it may affect timing of the repair**. Significant inflammation, infection, or induration around the fistula may mitigate against immediate repair. **Relevant vaginal anatomy, including depth, associated**

prolapse, atrophy, and introital size are carefully recorded, because these may affect the surgical approach to repair. Anatomically, fistulae located high in the vagina, at the level of the hysterectomy cuff in a deep narrow vagina, may be best approached by some surgeons abdominally because a vaginal approach in these patients can be challenging. Postmenopausal vaginal atrophy may be treated with preoperative topical estrogen replacement, thereby optimizing the health and vascularity of potential reconstructive flaps. Palpation for masses or other pelvic pathology, which may require attention at the time of fistula repair, is also performed. Notation of prior incisions in the perineum, lower abdomen, and thigh is necessary because these tissues may be required for flap reconstruction when definitive repair is undertaken.

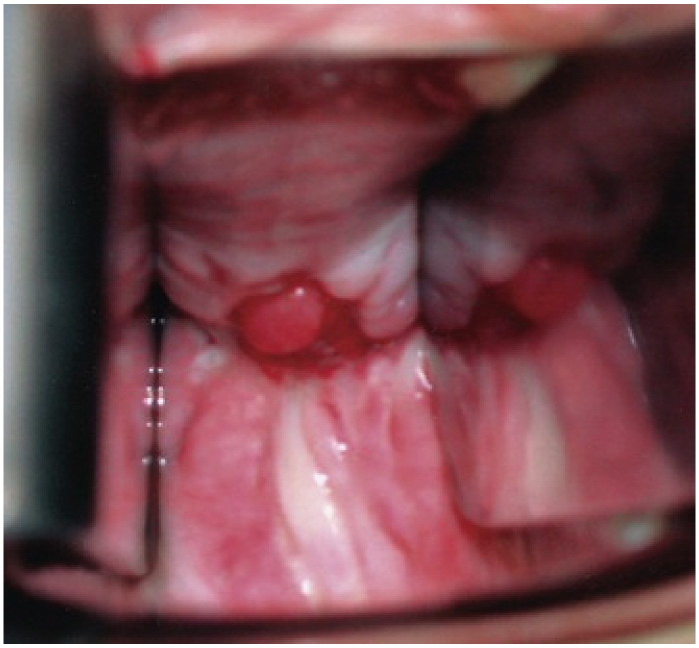

FIG. 129.4 Vesicovaginal fistula (VVF) on physical examination. A large VVF is seen at the apex of the vagina after hysterectomy. The VVF in this image is seen as reddish pink bladder mucosa prolapsing into the vagina. Handheld Heaney right-angled retractors provide lateral retraction in this image.

The presence of a VVF may be confirmed by instilling a vital blue dye into the bladder per urethra and observing whether vaginal drainage is discolored. Small or occult fistulae may be identified in this fashion (Drutz and Mainprize, 1988; Hanash et al., 2003). The vagina may be packed with gauze (3-swab test) or directly inspected for blue-tinged leakage (Gannon, 1990). If blue-tinged leakage is not apparent and the diagnosis of VVF is in doubt, the sensitivity of this test may be improved by ambulating the patient for a short period of time. Staining at the introital (distal) end of the packing suggests urinary incontinence or a urethrovaginal fistula, whereas proximal staining suggests a VVF. **If the vaginal packing remains dye free with this maneuver, then the possibility of a ureterovaginal fistula can be investigated with the use of clean vaginal packing, intravenous indigo carmine (or other vital dye), and a repeat pad test. Blue staining at the proximal end of the pad after this maneuver suggests the presence of a ureterovaginal fistula.**

A double dye or tampon test may confirm the diagnosis of urinary fistula, as well as suggesting the possibility of an associated ureterovaginal or urethrovaginal fistula (Hanash et al., 2003; Moir, 1973; Raghavaiah, 1974**)**. In one variation of the double dye test, a tampon is placed in the vagina. Oral phenazopyridine is administered, and vital blue dye is instilled into the bladder. If the tampon is discolored yellow-orange at the top, it is suggestive of a ureterovaginal fistula. Blue discoloration in the midportion of the tampon suggests VVF, whereas blue staining at the bottom suggests a urethrovaginal fistula.

Clear vaginal discharge after hysterectomy does not invariably represent a urinary fistula or incontinence. Other than normal vaginal secretions, less common causes include a peritoneovaginal fistula (Ginsberg et al., 1998), lymphatic fistula (Lau and Wong, 1994), vaginitis, and fallopian tube fluid (Maloney et al., 2016). Incontinence after cesarean section, in which a VVF has been excluded, may suggest the possibility of a ureterovaginal or vesicouterine fistula.

Cystoscopy

An endoscopic examination should be performed in patients for whom a suspicion of VVF is present (Fig. 129.5). Immature fistulae may appear as areas of localized bullous edema without distinct ostia. Mature fistulae may have smooth margins with variably sized ostia. In some cases, multiple pits and cavities along an area of the traumatized posterior bladder wall, in the setting of a small VVF, may make it difficult to identify the exact fistula tract. In these cases, a guidewire or ureteral catheter may be placed through the working channel of the cystoscope and into the fistula tract (Fig. 129.6). Visualization of the wire in the vagina confirms the exact location of the VVF on the bladder and genital sides. Cystourethroscopy can confirm the presence of the fistula but also may reveal the size of the tract, the presence of collateral fistulae, and the location of the ureteric orifices in relation to the fistula. **In the setting of a prior history of pelvic malignancy, a biopsy of the fistula is often done to evaluate for the possibility of a recurrent malignancy.** Fistulae located near or at the ureteric orifice may require ureteral reimplantation at the time of VVF repair. This type of requirement would usually mitigate against a completely transvaginal attempt at repair.

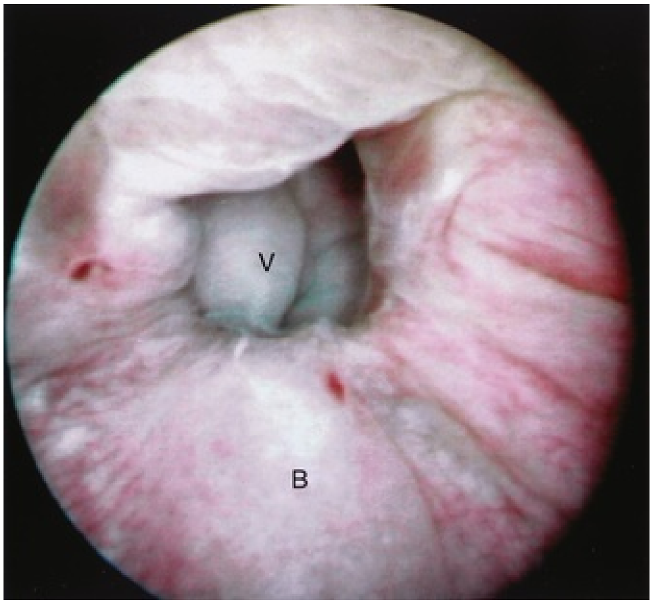

FIG. 129.5 Endoscopic view of vesicovaginal fistula (VVF). The fistula is now seen from the bladder side. This VVF is large enough to allow one to see directly into the vagina *(V)* through the bladder *(B).*

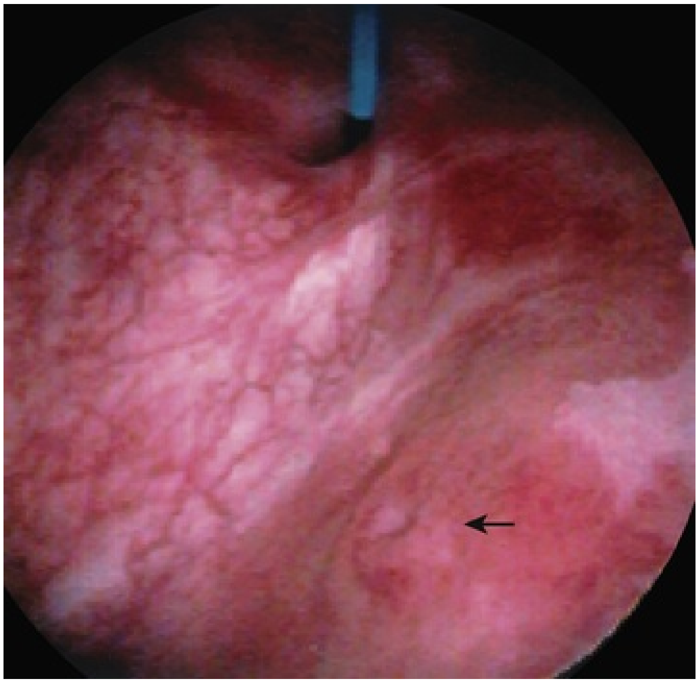

FIG. 129.6 Confirmation of a vesicovaginal fistula (VVF). A 4-Fr ureteral catheter traverses the fistula tract in this endoscopic photograph. The VVF is high on the posterior bladder wall, the typical location for a posthysterectomy VVF. The right ureter can be seen *(arrow)*.

Imaging

Contrast CT or magnetic resonance imaging (MRI) examination is usually performed if fistulae are suspected (Abou-El-Ghar et al., 2012; Verma et al., 2012). Delayed CT visualization of contrast within the vagina is considered highly suspicious for VVF in the majority of cases (Fig. 129.7). In cases of suspected VVF, CT should be performed with only intravenous contrast, or, alternatively, a CT cystogram can be performed to isolate the bladder. A vaginal tampon placed per vagina during intravenous urography (IVU) or CT scan may improve the sensitivity for finding small or occult VVF in patients with an otherwise negative evaluation. **Cross-sectional imaging may also be helpful in assessing for recurrent malignant disease in those with such a history. A cystogram and/or voiding cystourethrogram (VCUG) and an upper tract study can be performed in patients being evaluated for a VVF, if MRI or CT is not available.** The cystogram may objectively determine the presence and location of the fistula. VVFs are often best seen in the lateral projection (Fig. 129.8) in which the bladder and vagina are not superimposed (Fig. 129.9). **However, voiding images may be necessary in some patients with small**

fistulae to demonstrate the VVF. A cystogram that fails to demonstrate a suspected VVF but lacks voiding images or postvoid images should be considered nondiagnostic. During voiding, care should be taken to exclude vaginal voiding or reflux of contrast from the introital region cephalad into the vagina, which would produce a falsely positive image. An involuntary bladder contraction can be provoked with rapid filling during cystography, and if the intravesical pressure rises sufficiently, this may also be sufficient to demonstrate a VVF when the filling images of the cystogram failed to demonstrate it. In some instances, a cystogram can also permit an assessment of bladder capacity (important in the setting of prior radiotherapy), cystocele, bladder neck competence, and vesicoureteral reflux, any of which may have an impact on operative repair.

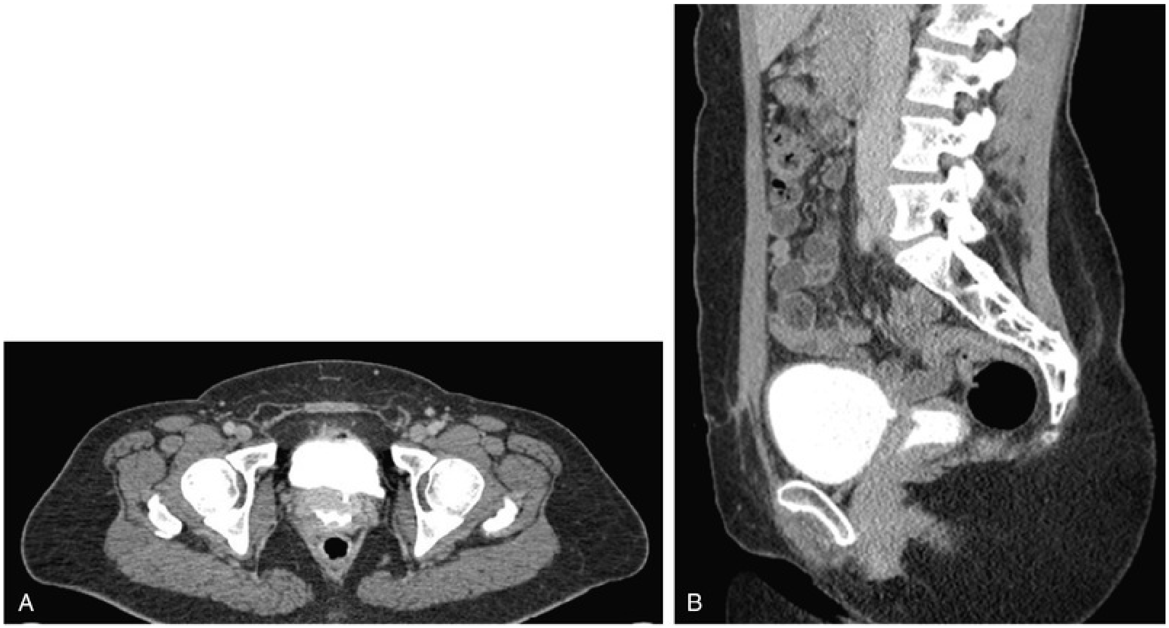

FIG. 129.7 Computed tomography (CT) scan of vesicovaginal fistula (VVF). (A) After intravenous administration of the contrast agent, there is high-density material in the bladder and vagina consistent with a VVF. The fistulous connection is between the bladder anteriorly and the vagina posteriorly. (B) Sagittal CT reconstruction demonstrating VVF.

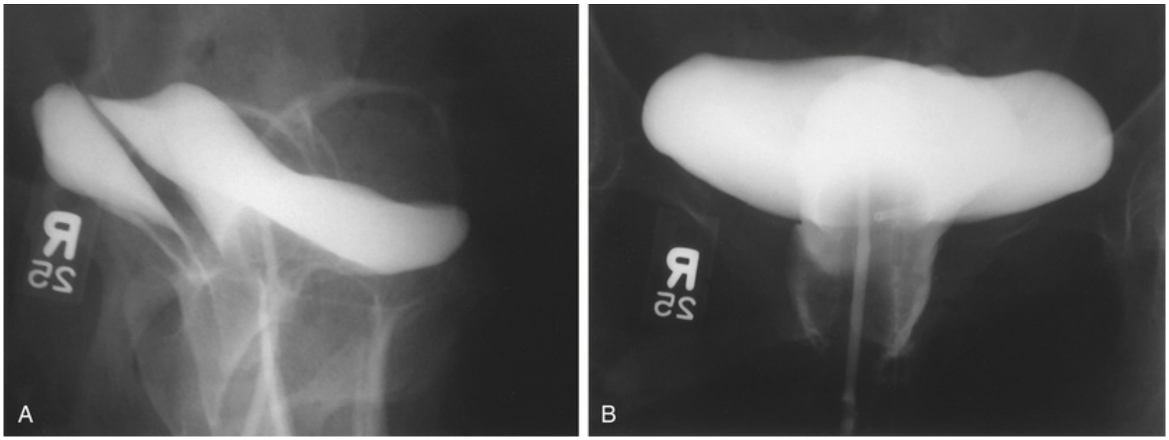

FIG. 129.8 Cystogram demonstrating a vesicovaginal fistula (VVF). (A) Lateral image demonstrates a posthysterectomy VVF. (B) Anteroposterior view. The contrast agent is seen opacifying and outlining the vagina, superimposed on the bladder.

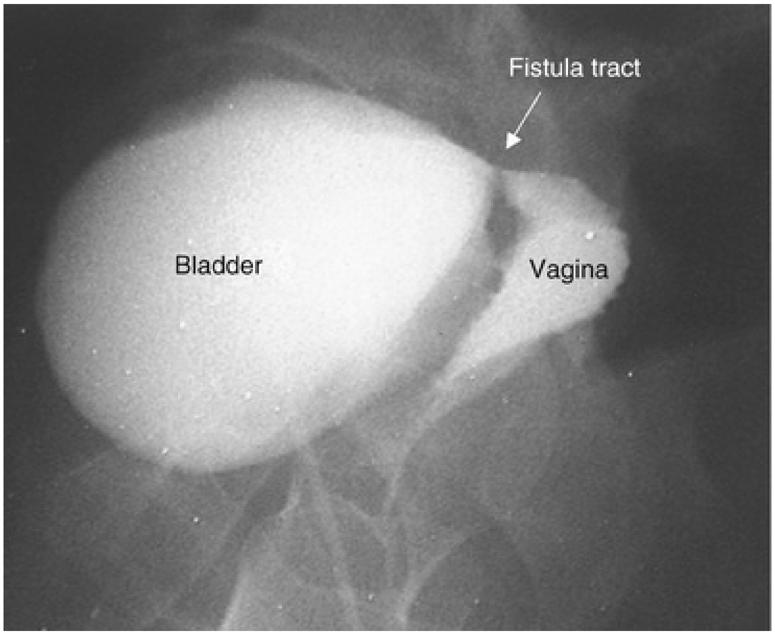

FIG. 129.9 Lateral image during cystography demonstrates the vesicovaginal fistula tract.

VVFs can be associated with ureteral injury or ureterovaginal fistula; thus upper urinary tract evaluation is important. CT urography or MRI studies reveal the combined fistulae (Botsikas et al., 2012; Lopez et al., 2005). IVU (Gerber and Schoenberg, 1993) may be an alternative if CT or MRI is not available.

Ultrasound examination has also been used as diagnostic tool but remains user dependent (Volkmer et al., 2000).

Other Studies

Appropriate urine studies including culture, and cytology when indicated, are performed. Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value with the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared with serum levels. When infection is detected, appropriate antibiotic coverage is initiated. Urodynamics, including video-urodynamics, are generally not necessary in the evaluation of routine posthysterectomy VVF. However, in the setting of a prior history of radiation or radical pelvic surgery (e.g., radical hysterectomy) or in those with preexisting neurogenic vesicourethral dysfunction, a urodynamic evaluation can be used to evaluate for significant detrusor dysfunction, including impaired bladder compliance, although the impact of these diagnoses on the management of VVF is not clear (Goh et al., 2013; Hilton, 1998).

Classification of Fistulae

An ideal fistula classification system should correlate with the outcome and prognosis of the eventual fistula treatment. The Waaldijk and Goh classifications are the only ones that have been used to document sufficient numbers of obstetric fistula patients. The Waaldijk classification assesses mainly the extent of the urethral involvement and whether the injury to the urethra is circumferential. Fistulae are classified into types I (distance between the distal edge of the fistula and the urethral meatus > 4 cm with no involvement of the urethral closure mechanism), II (distance between the distal edge of the fistula and the urethral meatus 1–4 cm [type IIA] or 0.5–1 cm [type IIB] with involvement of the urethral closing mechanism at the bladder neck and mid-urethral level), and III. Type III fistulae are those fistulae other than vesicovaginal fistulae and include rectovaginal fistulae and ureterovaginal fistulae.

Similarly, the Goh classification looks at three of the four proven variables known to affect the outcome for obstetric fistula repair: the location of the fistula (assessing the extent of urethral involvement), the size of the fistula, and the amount of scarring (including whether or not it is circumferential) (Browning, 2006; Goh, 2004; Goh et al., 2008). Bladder capacity or size is also known to affect outcome, but because this is difficult or even impossible to measure preoperatively, it has not been included in the Goh classification (Fig. 129.10).

FIG. 129.10 Goh classification.

There has been one comparative study showing that the Goh system is superior to the Waaldijk in terms of predicting closure (Capes et al., 2012; Goh et al., 2009). Frajzyngier et al. (2013), in a prospective cohort study, compared the classification systems of Lawson, Tafesse, Goh, Waaldijk, and the World Health Organization (WHO). They included 1274 patients in 11 centers. The predictive accuracy for fistula closure was 0.63 for the WHO score, 0.62 for Goh, and 0.60 for the Tafesse score. The Waaldijk and Lawson systems fared worse. They propose a new empirical and simplified scoring system. They also suggested including other items in a prognostic scoring systems such as HIV status, malnutrition, malaria, and genital cutting.

Classification systems have been developed for an obstetric fistula population. For iatrogenic fistulae the classification is highly variable. Most centers use their own classification. It may be possible to use OF classifications for iatrogenic fistula as well, although a recent study indicated that this is not the case for the Goh classification (Beardmore-Gray et al., 2017).

Treatment

Conservative and Minimally Invasive Therapy

The goal of treatment of VVF is the rapid cessation of urinary leakage with return of normal and complete urinary and genital function. The physical and psychological impact of a VVF can be overwhelming because of the continual wetness, undesirable odor, vaginal and bladder infections, and their related discomfort. Bladder catheterization may temporize some of these effects until definitive repair is undertaken but often will not completely eradicate leakage, especially in those with a large fistula or those with significant detrusor overactivity. Furthermore, catheterization may provoke additional irritation and pelvic pain and is a constant reminder to the patient of an iatrogenic insult.

Before epithelialization is complete, an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. **A trial of indwelling catheterization and anticholinergic medication for at least 2 to 6 weeks may be warranted in selected patients with newly diagnosed VVF, because spontaneous healing may result.**

Bazi (2007) reported a non-systematic review of papers including information on the spontaneous fistula closure of VVF. Although quality of the data was poor, he identified 30 studies from which 12 could be included (Bazi, 2007). Few studies described catheter drainage in large fistulae, although it seemed that those of less than 1 cm diameter were most likely to heal spontaneously. The time between the insult and institution of drainage in cases of nonsurgical closure varied widely, although in most cases this was less than 3 weeks. Similarly, the duration of catheterization before the initiation of conservative treatment was deemed to have been unsuccessful and varied considerably, making true estimates of the effectiveness of this approach impossible; generally this varied between 10 days and 3 months. Reported success rates varied between 0 and 100% (but 5 series had a sample size of 1), although in several series it was difficult to determine how many women had attempted conservative management.

In large series of obstetric fistulae in which a consistent approach to conservative management has been applied, spontaneous healing has been reported in up to 28% of cases (Waaldijk, 1994, 1997, 2004). In one series of urogenital fistulae of varying causes, spontaneous closure was seen in 19 of 238 or 8.0% of surgical cases, 4 of 38 or 10.5% of obstetric cases, 1 of 36 or 2.8% of miscellaneous (largely traumatic cases), and 0 of 34 or 0.0 of radiotherapy-related cases (Hilton, 2011). Oakley et al. (2014) studied 226 patients, of whom 116 underwent immediate surgery and 60 were treated with catheterization for 12 weeks. Of the conservative treatment group only 11.7% resolved spontaneously, the remainder required surgery. It is possible that in this, and many other reported, series data are an underestimate of the value of this approach to management (Hilton, 2011); nevertheless, combining available data gives an overall spontaneous closure rate from 348 surgical fistulae treated by initial catheterization of 13% ± 23% (Chittacharoen and Theppisai, 1993; Davits and Miranda, 1991; Dogra and Nabi, 2001; Falk and Orkin, 1957; Frang and Jilling, 1983; Gorrea et al., 1985; Hilton, 2011; Latzko, 1942; Lentz, 2005; Mathevet et al., 2001; Milicic et al., 2001; Soong and Lim, 1997, Tancer, 1992). Patients with ongoing, continuous vaginal leakage despite a functioning indwelling catheter should be spared prolonged catheter drainage and proceed with more definitive repair as soon as medically appropriate (Fig. 129.11).

Patients with small epithelialized fistulae may benefit from a minimally invasive treatment involving disruption of the epithelial layer of the fistula tract. Catheterization may be combined with minimally invasive electrocoagulation of the fistula tract. In this approach, a small cautery electrode is passed into the fistula tract endoscopically as far as possible. The electrode is slowly withdrawn from the tract with the electrode set on coagulation. The edges of the fistula tract should blanch. This approach was advocated by O'Conor as far back as 1938 for small, highly situated fistulae (O'Conor and Sokol, 1951) and has been reported in several small case series. In patients with fistulae less than 3.5 mm in diameter, 11 of 15 had successful fistula tract ablation with cauterization and catheter drainage in a study by Stovsky et al. (1994). Endoscopic transvesical VVF fulguration may be a safe and effective procedure for small VVFs on a day care basis, with decreased morbidity, improved cosmesis, and decreased hospital stay (Shah, 2010). Also, laser welding has been tried with success in a small series of women with fistula smaller than 3 mm (Dogra and Saini, 2011). All successfully treated patients had VVF less than 3 mm in diameter; in two patients with 6-mm VVF this approach failed. In patients with a thin vesicovaginal septum, large VVF, a nonoblique fistula tract, or significant inflammation around the fistula tract, fulguration risks failure and the possibility of enlarging the size of the fistula. This approach may also devitalize adjacent tissues, thereby compromising their future use as flaps. Fibrin sealant has been used as an adjunctive measure to treat VVF. The fibrin sealant may be injected directly into the fistula tract after fulguration as described earlier. The bladder is then drained for several weeks. Presumably, the gel-like nature of the fibrin sealant plugs the hole until tissue ingrowth occurs from the edges of the fistula (D'Arcy and Jaffry, 2010; Dolay et al., 2007; Kanaoka et al., 2001; Pettersson et al., 1979). In general, these conservative measures are useful for small, oblique fistulae (usually less than 2 to 3 mm in diameter), in patients who are agreeable to this course of therapy.

Surgical Repair

It has been stated that the best opportunity to achieve successful repair of VVF is with the initial operation (Elkins, 1994). Previous failed attempts at repair produce scarring and anatomic distortion and may compromise potential reconstructive flaps. Therefore careful preoperative planning is essential to maximize the chances for a successful result. **There is no “best” approach for all patients with VVF.**

Timing: Immediate Versus Delayed Repair

The timing of VVF repair is somewhat controversial. **Repair of VVF should be as expeditious as possible to minimize patient suffering; however, optimal timing for repair should allow consideration of certain medical and surgical factors.** It is generally accepted that VVF resulting from obstructed labor should be associated with a 3- to 6-month delay before definitive repair (Arrowsmith, 1994; Waaldijk, 1994; Wein et al., 1980) to allow maximum demarcation of ischemic tissue and resolution of the associated edema and inflammatory reaction. Longer periods of time, up to 6 to 12 months, have been advocated for radiation-induced fistulae, which are often associated with severe obliterative endarteritis and reduced tissue vascularity.

In the classical teaching of VVF, a minimal waiting period of several months is suggested—from the inciting event before the definitive repair attempt—to allow reduced tissue edema and inflammation, and optimal pliability of the tissues (Lawson, 1972; Persky et al., 1979). O'Conor (1973) recommended a waiting period of 3 to 6 months for suprapubic VVF repairs. In this setting, reduced inflammation and edema permit easier identification of tissue planes (and therefore flap development), less bleeding, and less tension on the reapproximated suture lines. **There is no consensus in the literature as to the definition of "early"** in this context, with different studies either failing to specify at all, or giving a broad range of definition. Although some studies have used the terms "immediate" (Lee et al., 2010), "less than 2 weeks" (Shelbaia and Hashish, 2007), or "less than 30 days" (Soong and Lim, 1997), most reports have considered either less than 6 weeks (Badenoch et al., 1987; Blandy et al., 1991; Kam et al., 2003) or less than 3 months (Moriel et al., 1993; Radoja et al., 2010; Wang and Hadley, 1990) as their definition of early intervention. **The enthusiasm for delayed management has waned, and, in general, uncomplicated postgynecologic urinary fistulae may be repaired as soon as they are identified and confirmed, thereby minimizing patient discomfort and anguish** (Blaivas et al., 1995; Kostakopoulos et al., 1998; Nagraj et al., 2007). Early repair can be considered within 2 to 3 weeks after the occurrence of the fistula. If that time window has passed, a waiting period of 2 to 3 months is considered to be safe. There are no good comparative studies to offer more guidance. Nevertheless, in some cases, the timing of a VVF repair is best tailored to the individual patient (Blaivas et al., 1995). If an abdominal approach is being considered after a particularly difficult or complicated abdominal surgery that resulted in the VVF (e.g., complicated by abscess, urinoma), then a delay may be warranted to allow resolution of active inflammation. Another potential reason to delay repair is to treat ongoing infection or inflammation at the level of the vaginal cuff. Periodic reexamination of the vaginal tissues can be performed every 1 to 2 weeks, and definitive repair scheduled when suitable pliability is noted (Carr and Webster, 1996).

A vaginal approach can be attempted as soon as 2 to 3 weeks after the initial injury, if conservative therapy fails (i.e., the patient remains wet when a Foley catheter is in place to provide adequate drainage of the bladder) and the patient is in good general health. The vaginal tissues are usually relatively undisturbed from the prior causative surgery, especially if the surgery was transabdominal. Wide, healthy vaginal flaps can usually be obtained. In the rare circumstance in which a VVF is seen within the first 24 to 48 hours postoperatively, an immediate repair can be attempted (Margolis and Mercer, 1994).

Approach: Abdominal Versus Vaginal

VVF may be repaired through a transvaginal or transabdominal (transvesical) approach. Each approach has merits depending on the particular circumstances of the fistula, and excellent outcomes can be expected with both approaches (Table 129.1). **Next to factors such as size, location, and the need for adjunctive procedures often influence the choice of approach, also the experience of the operating surgeon must be taken into account.** There are no randomized studies comparing abdominal and vaginal approaches, although there are recent retrospective studies comparing vagina and abdominal approaches. The fistula closure rate seems to be similar for both approaches (Gedik et al., 2015; Rajamaheswari et al., 2012; Tatar et al., 2017). Also the postoperative sexual function is similar in both approaches (Mohr et al., 2014). However, the abdominal route is characterized by higher morbidity (22% vs. 7%), prolonged length of stay (3.5 days ± 2.3 vs. 1.6 days ± 2), more sepsis (4.3% vs. 0), a higher transfusion need (7.1% vs. 0.8%), and a higher readmission rate (10.1% vs. 0.8%), when compared with the vaginal approach (Theofanides et al., 2017). **The abdominal approach is a significant predictor of complications at 30 days. Therefore a vaginal approach is to be recommended or referral to a skilled vaginal surgeon should be offered.**

TABLE 129.1

Abdominal Versus Transvaginal Repair of Vesicovaginal Fistulae

	ABDOMINAL	**TRANSVAGINAL**
Incision	Abdominal incision	Vaginal incision(s) can be done immediately in the absence of infection or other complications.
Timing of repair (elapsed time from fistula creation)	Eventually within 2–3 weeks, but often delayed 3–6 months	
Exposure	Fistula located low on the trigone or near the bladder neck may be difficult to expose transabdominally.	Fistula located high at the vaginal cuff may be difficult to expose transvaginally.
Location of ureters relative to fistula tract	Fistula located near ureteric orifice may necessitate reimplantation.	Reimplantation may not be necessary even if fistula tract is located near ureteric orifice.

Sexual function	No change in vaginal depth	Risk of vaginal shortening (e.g., Latzko technique)
Use of adjunctive flaps	Omentum, peritoneal flap, rectus abdominis flap	Labial fat pad (Martius fat pad), peritoneal flap, gluteal skin or gracilis myocutaneous flap
Relative indications	Large fistulae, location high in a deep narrow vagina, radiation fistulae, failed transvaginal approach, small-capacity bladder requiring augmentation, need for ureteral reimplantation, inability to place patient in the lithotomy position	Uncomplicated fistulae, low fistulae
Complications	Higher morbidity Increased length of stay Higher transfusion need Higher readmission rate Higher risk for sepsis	Vaginal shortening
Cost	High	Low

Potential disadvantages of the transvaginal approach include the relative lack of familiarity of the vaginal cuff anatomy to many urologists; the potential for vaginal shortening, especially with the Latzko approach; and, finally, the difficulty in exposing high or retracted fistulae located near the vaginal cuff, especially in deep, narrow vaginas, or in those without any apical prolapse, such as that found in nulliparous females (see Fig. 129.3).

The abdominal approach to VVF repair can be indicated in several circumstances. If the VVF is associated with **other intra-abdominal pathology requiring repair—**including an associated ureteral injury (i.e., ureterovaginal fistula) or a complex fistula, including those involving another intra-abdominal organ—then a transabdominal approach is indicated to address the problems simultaneously. In patients with **a small-capacity or poorly compliant bladder (often secondary to radiation) requiring augmentation cystoplasty,** an abdominal approach is indicated, because both procedures can be performed using the same incision. Currently the open abdominal approach is often being replaced by laparoscopic or robotic repairs (see later).

Handling of Fistula Tract: Excision Versus No Excision

A long-held tenet for successful fistula closure, dating back to the original description by Sims in 1852, involves complete excision of the fistulous scar tissue and tract (Persky and Rabin, 1973). This approach ensures clean, well-vascularized viable edges to be approximated for the initial layer of repair but increases the fistula size. **However, excision of the fistula tract is not always necessary and may even compromise the repair in some patients** (Raz et al., 1993; Shaker et al., 2011). There is only a single randomized trial comparing aspects of surgical technique; Shaker et al. (2011) reported a randomized controlled trial (RCT) comparing trimming of the fistula edge with no trimming. Although there was no statistical difference in success rates between the two groups, in patients in whom repair was unsuccessful and trimming had been undertaken, the fistula tended to become larger, whereas fistulae wherein there was no trimming were more likely to be smaller on recurrence. There are several potential disadvantages of excision of the fistula tract. First, this creates a larger soft-tissue defect to be repaired. Excision of the fibrous tract may lead to bleeding, which, if cautery is used, may result in tissue necrosis and impede healing (Eilber et al., 2003).

If the VVF is adjacent to the ureter, then excision of the tract may mandate reimplantation of the ureter. Alternatively, if the tract is left in situ, the ureter may be catheterized for the repair and then left undisturbed during a transvaginal operation, obviating the need for reimplantation. In addition, in chronic fistulae, a strong fibrous ring forms outside the epithelialized tract, which maintains some strength through the repair if this layer is incorporated into the closure. This can be an important consideration in patients with significant detrusor overactivity postoperatively from either the repair or the indwelling drainage catheters.

Use of Adjuvant Flaps or Grafts: Type and Application

Before embarking on surgical repair, the surgeon should be familiar with a variety of adjuvant flaps and grafts that allow for the interposition of healthy tissue during VVF repair. It is often not possible to predict which patients will require these procedures. The literature consists of retrospective cohort series or small comparative studies, and thus there is no evidence that a Martius or any other interposition graft improves the outcome in primary fistula repair. Likewise there is no evidence that it does not.

The indications for tissue interposition are not well defined, but these measures are most commonly used in the setting of irradiated tissues, obstetric fistulae, failed prior repairs, large fistulae, and patients with

tenuous repairs. A variety of other flaps including gracilis muscle flaps, labial myocutaneous flaps, seromuscular intestinal flaps, and rectus abdominis flaps, as well as free grafts of bladder mucosa, have been used as adjunctive measures in the repair of complex VVF (Brandt et al., 1998; Izes et al., 1992; Menchaca et al., 1990; Mraz and Sutory, 1994; Ostad et al., 1998; Sharifi-Aghdas et al., 2002; Symmonds and Hill, 1978; Viennas et al., 1995). The various types of flaps are discussed in more detail later in the chapter.

Other Considerations

There is no evidence that preoperative estrogen supplementation is beneficial in the postmenopausal patient with vaginal atrophy and VVF. There is some evidence that estrogen supplementation may improve spontaneous closure of fistulae (Goh et al., 2001; Park et al., 2015), but there is no proven effect on the outcome of surgical repairs.

Perioperative antibiotics are administered, according to the existing American Urological Association or European Association of Urology guidelines on vaginal surgery. Specifically for obstetric fistula Muleta et al. (2010) showed in an RCT that a single prophylactic dose of gentamycin was as effective as the extended use of amoxicillin, chloramphenicol, or cotrimoxazole. Treatment of existing infection based on preoperative urine culture is potentially beneficial in preventing bacteremia during surgery.

Sexual activity should be documented preoperatively. Patients should be specifically queried regarding sexual function and dyspareunia occurring before the onset of the event that resulted in the fistula. Fistula repair usually improves sexuality (Mohr et al., 2014), but women need to be counseled that some types of vaginal procedures for the repair of VVF (such as Latzko partial colpocleisis) and abdominal repairs may result in vaginal shortening and postoperative dyspareunia. Preoperative documentation of this preexisting condition can be invaluable. Furthermore, adjuvant procedures that may alter vaginal appearance or function, such as the harvesting of a Martius fibrofatty labial flap or an episiotomy, should be carefully discussed with the patient in advance, especially regarding sexual function, although the impact on sexuality of the Martius flap is limited (Malde et al., 2017; Wilson et al., 2017).

Finally, postoperative drainage after VVF repair should be offered by a transurethral catheter (Leng et al., 1998), a suprapubic catheter (Blaivas et al., 1995), or a combination of both (Eilber et al., 2003). The duration of catheterization is variable. Ruminjo et al. (2014) did a survey among African and

Asian fistula centers and showed that catheters are kept between 14 and 29 days. Nardos showed that 10 days of catheterization are not inferior to 14 days (Nardos et al., 2012). A cystography may be used to establish the optimal timing of catheter removal (Bochenska and Zyczynski, 2016).

Preoperative Counseling and Indications for Surgery

Surgical repair of a VVF is indicated after confirmation of the diagnosis. As noted previously, a trial of conservative management may be warranted in selected cases, especially in those with a newly diagnosed, small, uncomplicated fistula in which the vaginal leakage significantly improves or resolves with catheter drainage. When conservative measures fail or if after adequate counseling the patient requests repair before a trial of conservative management, surgical treatment is pursued. Before surgery, patients should be counseled that VVFs in the industrialized world are repaired on the first attempt in more than 85% of cases; however, prolonged postoperative urinary catheter drainage is necessary after surgery. Postoperative urinary urgency and frequency are common for a period of time after removal of the catheter but are usually self-limited. Finally, the patient should be aware that it may be necessary to alter the surgical plan intraoperatively as a result of a variety of factors encountered during the operation, and that interpositional flaps or grafts may be used. Comparing the outcomes of treatment between different reports and different methods is made difficult by the inconsistent and relatively inefficient outcome measures used. These have ranged from the apparent achievement of a watertight repair based on dye-testing in the operating theatre, to patient reported symptoms at the time of discharge from hospital. Follow-up in obstetric fistula patients is inevitably difficult in many developing world centers, but even among surgical or radiotherapy cases in the developed world, relatively few reports describe examination findings or symptoms at later postoperative review. Long-term outcomes and quality-of-life measures have only rarely been reported (Browning and Menber, 2008, Dolan et al., 2008).

Vaginal Techniques

Common vaginal approaches to the repair of uncomplicated VVF are described. The merits of the vaginal approach are reviewed in Table 129.1. There are two main types of closure technique applied to the repair of urinary fistulae: the *classical saucerization* technique described by Sims (1852) and subsequently modified as a *partial colpocleisis* by Latzko (1942) and the more commonly used *dissection and repair in layers* or “*flap-splitting*” technique (variously attributed to Hayward, Collis, and Lawson Tait) (Wall, 2005). Individual surgeons inevitably employ these techniques somewhat variably, and in different situations, and there are no data comparing their outcomes.

Vaginal Flap or Flap-Splitting Technique.

The vaginal flap or flap-splitting approach popularized by Raz and colleagues (Raz et al., 1993; Zimmern et al., 1985) results in a three-layer closure without the use of an adjuvant flap, and a four-layer closure if a flap is used (Fig. 129.12). It can be performed as an outpatient procedure and is applicable to most simple, uncomplicated VVFs (Fig. 129.13). The number of layers to be used is not an absolute given. Good dissection of the vaginal wall and the fistula, allowing for tension-free closure of well vascularized bladder wall and vaginal wall, seems to be more important than the use of additional layers or interposition flaps (Browning, 2006; Miklos et al., 2015).

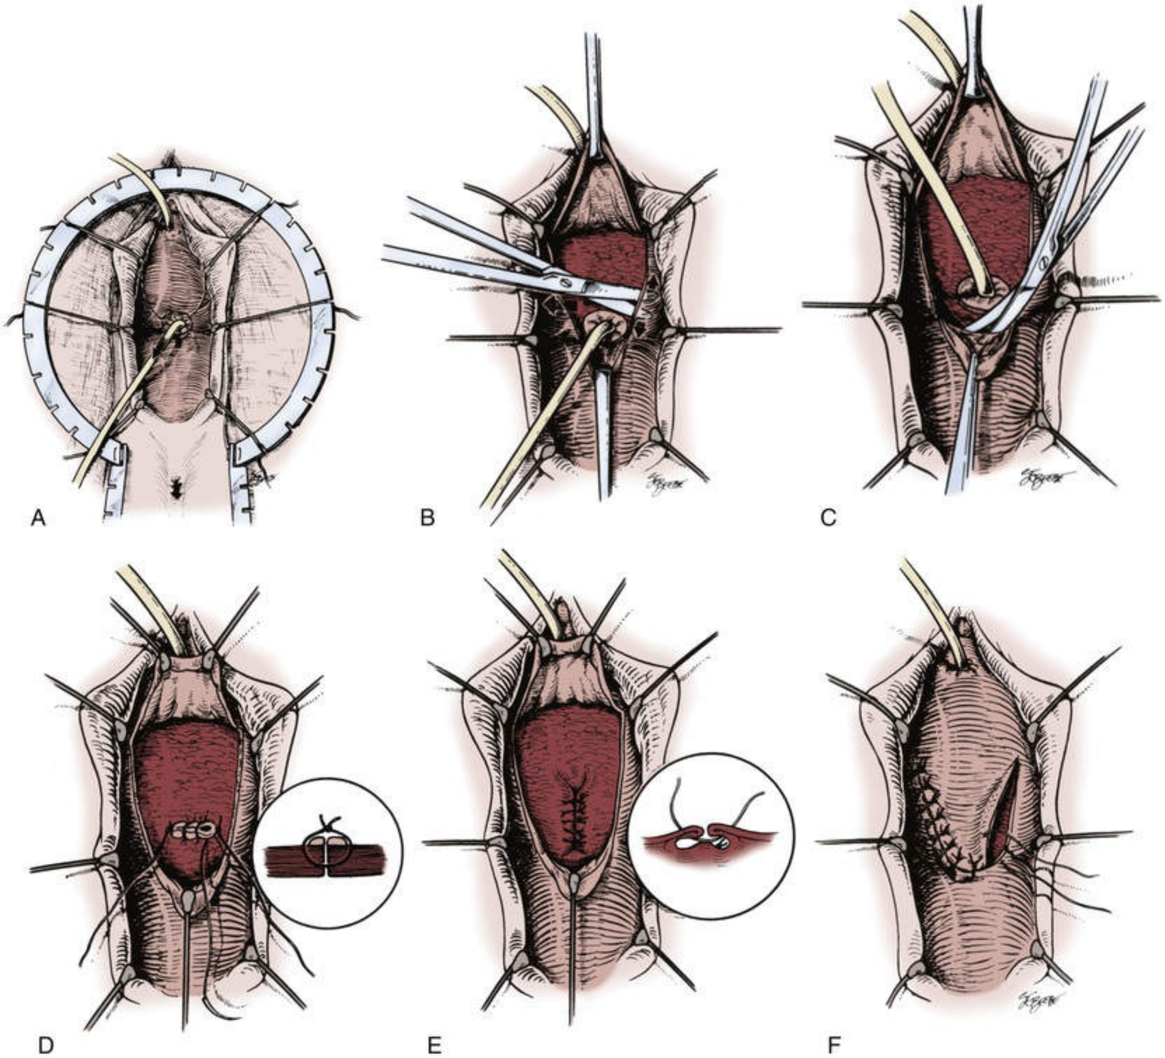

FIG. 129.12 Technique of vaginal repair of a posthysterectomy vesicovaginal fistula (VVF). (A) Retraction including ring retractor, vaginal speculum, and Foley catheter in the VVF tract. A Foley catheter is seen in the VVF tract providing traction on the vaginal cuff. (B) Mobilization of anterior vaginal wall flap. Lateral flaps are developed as well, thereby isolating the VVF tract. (C) Mobilization of posterior vaginal wall flap. (D) Initial layer of closure is performed without excising the edges of the fistula tract. (E) The perivesical fascia is closed with Lembert-type sutures. This line of closure is perpendicular to the initial suture line. (F) The vaginal wall flaps are advanced to avoid overlapping suture lines. (From Ganabathi K, Sirls L, Zimmern P, et al.: Vesicovaginal fistulae: reconstructive techniques. In McAninch J, editor: *Traumatic and reconstructive urology,* Philadelphia, 1996, Saunders; p 317.)

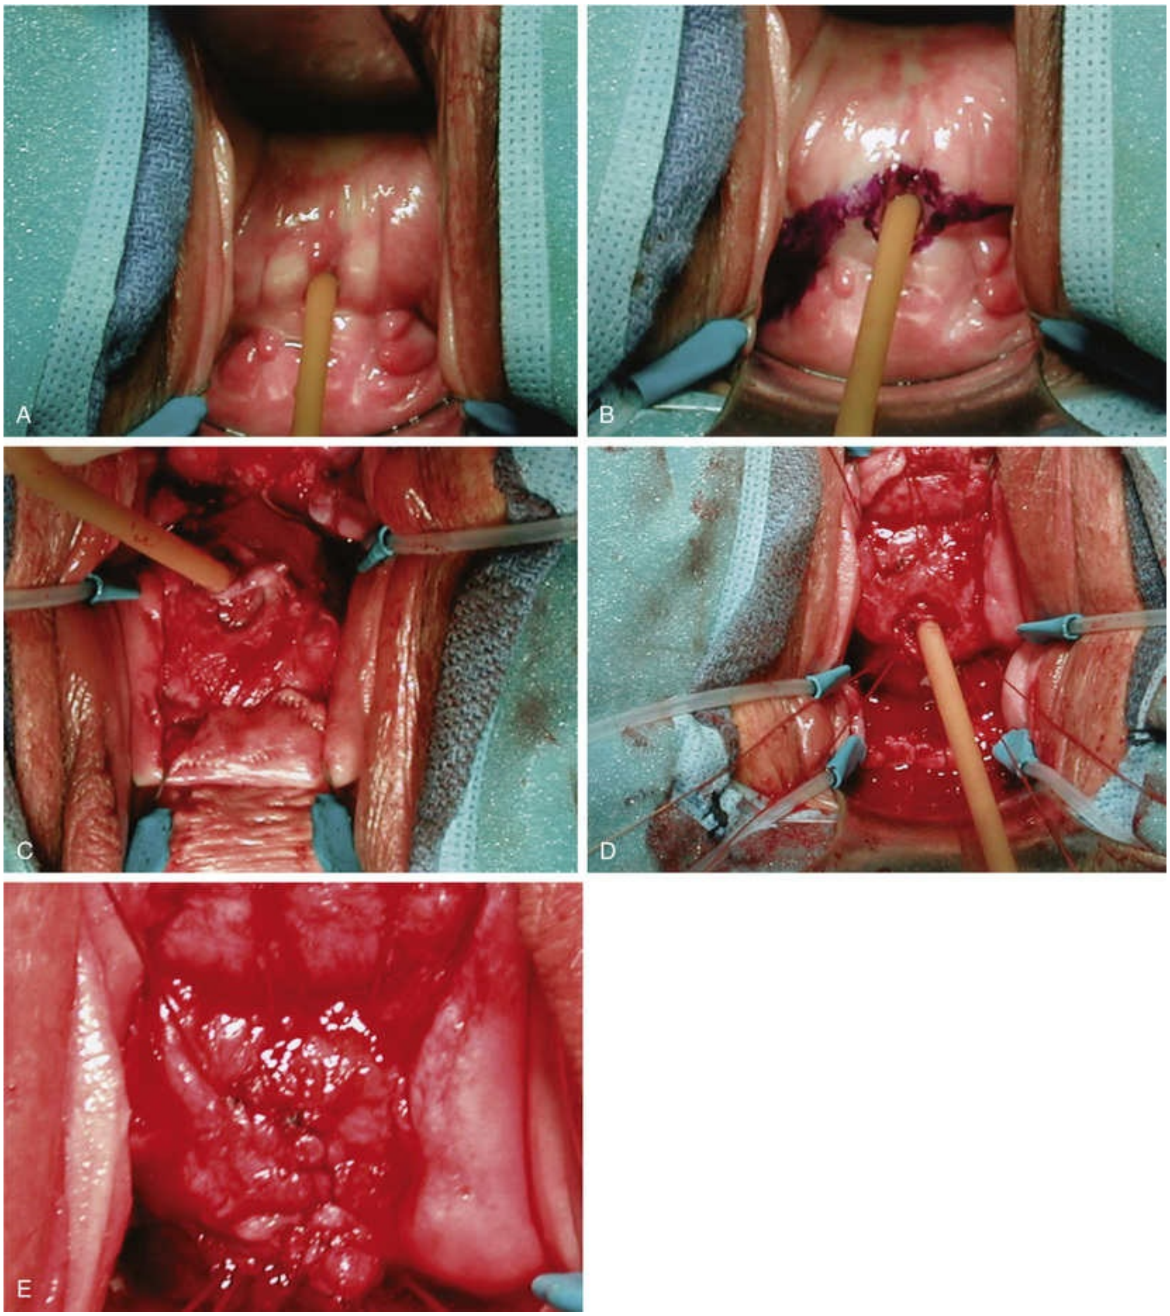

FIG. 129.13 Operative repair of vesicovaginal fistula. (A) Foley catheter in fistula providing retraction. (B) Posterior vaginal flap is marked. (C) The vaginal flaps have been developed and are retracted behind the hooks of the ring retractor. Note that the fistula tract is intact surrounding the Foley catheter. (D) The first layer of sutures has been placed. The Foley catheter will be removed from the fistula tract and the sutures tied down. (E) The second layer of closure is performed by reapproximating the perivesical fascia over the first suture line.

Complications.

Proper surgical technique is critical in avoiding complications. Dissection in the proper surgical planes ensures minimal bleeding. When significant bleeding is encountered during the dissection, it is possible that an improper plane of dissection was entered. Careful intraoperative inspection and reevaluation of the surgical planes are warranted. Furthermore, excessive use of cautery may compromise the vascular supply of the tissue flaps used for repair. This may become evident only in the postoperative period with ischemic flaps and recurrence of the fistula. Intraoperative bleeding should be controlled with fine absorbable suture whenever possible. **The possibility of ureteral injury is a concern if the VVF is located adjacent to the insertion of the ureter.** If there is doubt regarding a ureteral injury, then cystoscopy should be performed after the intravenous administration of indigo carmine. Blue efflux from the ureteric orifice confirms ureteral patency. Alternatively, retrograde imaging can be performed, because the ureter can be patent but partially obstructed.

Long-term complications from transvaginal VVF repair include vaginal shortening and stenosis. Careful attention to flap mobilization and reconstruction will minimize this complication. In addition, excessive resection of the vaginal wall should be avoided during reconstruction to avoid vaginal shortening or scarring.

The most important complication of VVF repair is recurrence of the fistula. A repeat transvaginal approach can be attempted with satisfactory success. A careful review of potential factors leading to failure of the initial repair is undertaken, and any remediable factors (e.g., inadequate nutrition, vaginal atrophy, excessive postoperative bladder spasms) are addressed. Strong consideration should be given to the use of adjuvant flaps in repeat VVF repairs in which tissue quality may be suboptimal.

Other Transvaginal Techniques.

There are multiple variations to transvaginal fistula repair, including those originally described by Latzko in 1914. The Latzko high-partial colpocleisis is a very popular approach among some reconstructive surgeons, with reported success rates in excess of 90% (Tancer, 1992). This approach may not be as successful as the vaginal flap technique for large obstetric fistulae (Elkins, 1994). In this procedure, the fistula tract is isolated, and the tissue surrounding the VVF tract is denuded of vaginal “epithelium” circumferentially for a distance of 1 to 2 cm. Care is taken to avoid deeply “denuding” the vaginal tissues to avoid entry into the bladder or perivesical fascia. The denuded areas are then reapproximated over the fistula tract with a series of interrupted absorbable sutures. Sutures are not placed into the detrusor or vesical mucosa, but rather in the bladder serosa. The edges of the vaginal wall are then reapproximated as a second layer, creating a partial colpocleisis in some patients. Advantages of the Latzko procedure include minimal blood loss, no need for ureteral reimplantation (even for a fistula adjacent to the ureter, because sutures are not placed through the bladder), and a short convalescence. Potential disadvantages include the possibility of vaginal shortening (Enzelsberger and Gitsch, 1991), as well as the creation of directly overlapping suture lines.

Webster and colleagues reported excellent results with a transvaginal approach to VVF by vaginal cuff excision (Flynn et al., 2004; Iselin and Webster, 1998). In this approach, the fistula tract is isolated, and the entire epithelialized portion of the tract is excised in the fashion of a wide inverted cone, leaving a funnel-shaped defect from the vesical to the vaginal side of the fistula. The defect is then closed in three or four layers using absorbable suture. The principal advantages of this technique are that mobilization of vaginal flaps is not required, and vaginal shortening is minimal.

Abdominal Techniques

VVF may be repaired transabdominally, and this is the preferred approach in those cases requiring augmentation cystoplasty or ureteral reimplantation. Compared with the vaginal approach, the abdominal approach to VVF repair is associated with a longer recovery time and in-patient hospitalization, greater blood loss, more cosmetic deformity, and, in general, greater morbidity. Abdominal repair of VVF may be performed intraperitoneally or extraperitoneally, as well as transvesically.

Suprapubic Intraperitoneal or Extraperitoneal Approach.

The patient is positioned in a low lithotomy position with access to the vagina in the sterile operative field. Ureteral catheters may be placed preoperatively or intraoperatively to assist in identification of the ureters, especially if the VVF is in close proximity to the ureteric orifices. A lower midline incision is carried out. As classically described by O'Conor and colleagues (Chibber et al., 2005; O'Conor, 1980; O'Conor and Sokol, 1951), the bladder is approached extraperitoneally; however, in some cases, the peritoneum will be entered. The bladder is opened vertically, and the cystotomy is extended down to the opening of the VVF (Fig. 129.14). As the dissection proceeds distally, stay sutures placed on the bladder edges greatly assist in retraction. In addition, a curved sponge stick placed per vagina with gentle upward traction can provide excellent exposure of the VVF. With the bladder having been bivalved down to the level of the VVF, the VVF tract is excised, and the dissection is continued beyond the fistula tract to develop the vesicovaginal space (Fig. 129.15). The vagina is carefully dissected and separated from the bladder for a distance of 2 to 3 cm beyond the VVF. **The key to the operation is the mobilization of the bladder from the vagina caudal to (beyond) the VVF tract.** After wide mobilization from the bladder, the vagina is closed with a running absorbable suture. At this point, if an interpositional flap of greater omentum is to be used, it is mobilized and then secured 1 to 2 cm distally beyond the excised VVF tract (see later discussion) (Wein et al., 1980).The bladder is then closed in one or several layers. A suprapubic tube and urethral catheter are usually left for postoperative drainage. Anticholinergic agents are used liberally in the postoperative period to minimize bladder irritability, which may be problematic.

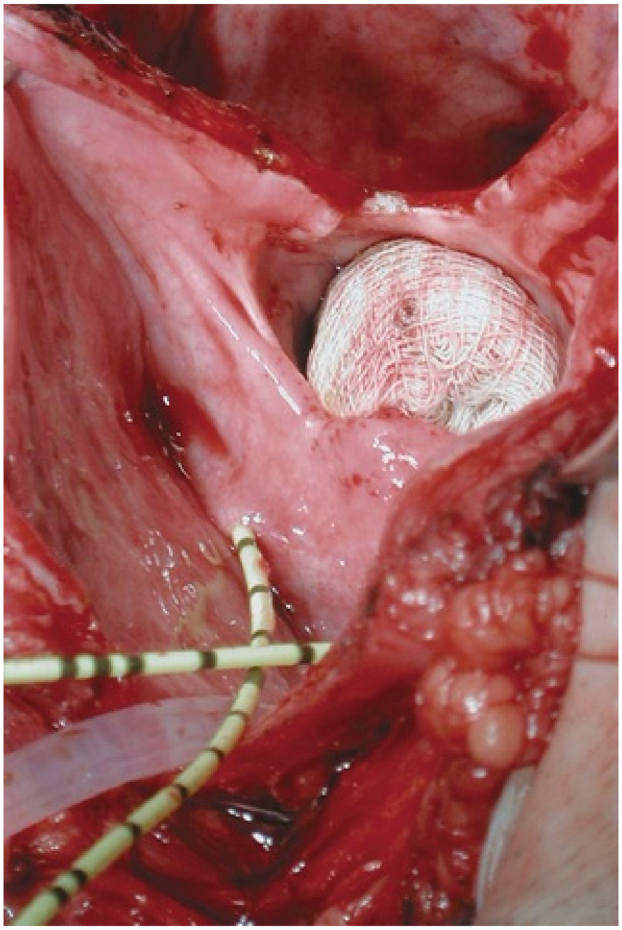

FIG. 129.14 Intraoperative photograph from a suprapubic vesicovaginal fistula (VVF) repair. The bladder has been opened anteriorly and bivalved in the midline down to the level of a very large VVF. The gauze packing lies in the vagina. The ureteral catheters were placed to identify the ureters intraoperatively.

(C) After closure of the vagina, the bladder is closed in multiple layers. (D) Omentum is interposed between the bladder and vaginal closures. (From Ganabathi K, Sirls L, Zimmern P, et al.: Vesicovaginal fistulae: reconstructive techniques. In McAninch J, editor: *Traumatic and reconstructive urology,* Philadelphia, 1996, Saunders, p 315.)

Bladder augmentation or ureteral reimplantation, if necessary, can be incorporated into the suprapubic approach before closure of the bladder. Large or small bowel may be used for augmentation cystoplasty, depending on the clinical circumstances.

Transvesical.

A suprapubic transvesical approach to VVF repair has also been described (Cetin et al., 1988; Gil-Vernet et al., 1989; Landes, 1979). In this approach, the bladder is opened through a vertical cystotomy but is not bivalved down to the VVF tract. From a transvesical approach, the VVF tract is circumscribed and excised transvesically. The vaginal edges are then carefully mobilized from the bladder. The vagina and bladder are closed sequentially. A V-shaped flap of adjacent posterior bladder wall may be brought down as a flap to close a large gap or to minimize overlapping suture lines (Gil-Vernet et al., 1989). This approach has been successful in simple and complex fistula (Gil-Vernet et al., 1989; Leng et al., 1998), and modifications have been described incorporating an omental flap (Hellenthal et al., 2007).

Laparoscopic and Robotic Approaches

Laparoscopic VVF repair is an alternative to the classical open approach described previously. Compared with the transabdominal approach, laparoscopic repair is reported to be associated with less surgical trauma, shorter convalescence, and lower morbidity without compromising the results (Ghosh et al., 2016; Nezhat et al., 1994; von Theobald et al., 1998; Xiong et al., 2016). Laparoscopic VVF repair is most useful in the same scenarios as the transabdominal repair, such as in the setting of a high VVF in which a vaginal operation would be anatomically challenging. Dense pelvic adhesions and/or inflammation from prior abdominal surgery can make this approach less desirable in some patients.

Successful robotic VVF repair was first reported in 2005 (Melamud et al., 2005), and several small case series have been subsequently reported with or without the use of interposition flaps (Kelly et al., 2017; Martini et al., 2016; Watts et al., 2017). A five-port technique has been described using a vaginal pack to maintain pneumoperitoneum throughout the case (Hemal et al., 2008; Sundaram et al., 2006). Removal of the vaginal packing without loss of pneumoperitoneum confirms successful closure. Advantages of the robotic technique include three-dimensional (3D) visualization, wristed instrumentation reducing the severe angulation required for laparoscopic VVF repair, and technically simpler intracorporeal knot tying. There is no level 1 evidence to prove superiority of one approach over another. Outcomes depend on the surgeon's experience and practice. Minimally invasive series demonstrate efficacy in primary VVF repair with acceptable success rates. Two retrospective studies described transition from open to laparoscopic repair and found that the latter was minimally invasive with similar success (Ou et al., 2004). In another retrospective case-matched study of 32 patients, Gupta et al. (2010) evaluated robotic-assisted laparoscopic versus open repair for recurrent VVF without any significant statistical difference in success rate (100% vs. 90%), mean operative time, complication rate, use of interpositional flap (omental vs. peritoneum), or complications (0 vs. 10%). The most significant difference between the two groups was shorter average hospitalization (3.1 vs. 5 days) favoring the robotic-assisted group, with decreased morbidity as opposed to open surgery (Gupta et al., 2010).

Miklos et al. (2015) performed a systematic review on laparoscopic and robotic fistula repair and concluded that the outcome of a transperitoneal approach is equal to a transvesical approach and that the number of layers or the use of interposition material had no influence on the fistula closure. Intraoperative integrity testing of the bladder led to better outcome (Table 129.2).

Although there have been no direct comparisons among the classical transabdominal VVF repair, transvaginal VVF repair, and the minimally invasive robotic and laparoscopic techniques, **it is doubtful that a single procedure will emerge as the optimal surgery for all patients with VVF, given the variability in the nature of the condition, the patients in whom it occurs, and the expertise of individual surgeons, but considering the morbidity and costs of abdominal approaches, vagina repair should be considered first, if possible.**

Adjuvant Procedures in the Repair of Vesicovaginal Fistulae: Tissue Interposition

The interposition of a healthy, well-vascularized tissue flap during VVF repair may be beneficial under certain circumstances. **Tissue flaps are especially helpful in the setting of complex fistulae, such as those that have recurred after a prior attempt at repair, those related to previous radiotherapy, ischemic or obstetric fistulae, large fistulae, and, finally, those associated with a difficult or tenuous closure because of poor tissue quality. In primary fistulae, adequate dissection allowing tension free and watertight closure of the bladder wall and vaginal wall are more important than the use of interposition material.** For VVFs repaired transvaginally, a labial fat pad (Martius flap) or a peritoneal flap is most commonly used. From a transabdominal approach, omentum or peritoneum is often used as an interpositional flap.

Martius Flap.

For low or distal fistulae, a Martius fibrofatty labial flap is a reliable source of tissue. The fibrofatty labial flap was first described by Heinrich Martius in 1928. **This flap consists of adipose tissue and connective tissue and is the preferential tissue for fistulae involving the trigone, bladder neck, and urethra** (Boronow, 1986; Ghoniem and Monga, 1995; Patil et al., 1980; Punekar et al., 1999). **The blood supply to the flap derives inferiorly from the posterior labial vessels (off the internal pudendal artery), superiorly from the external pudendal artery, and laterally from the obturator artery.** The lateral blood supply is sacrificed during mobilization of the flap; the flap may be divided at either its most superior or inferior margin (basing the blood supply on the inferior or superior vascular pedicle, respectively), depending on where the flap will be transferred (Figs. 129.16 and 129.17).

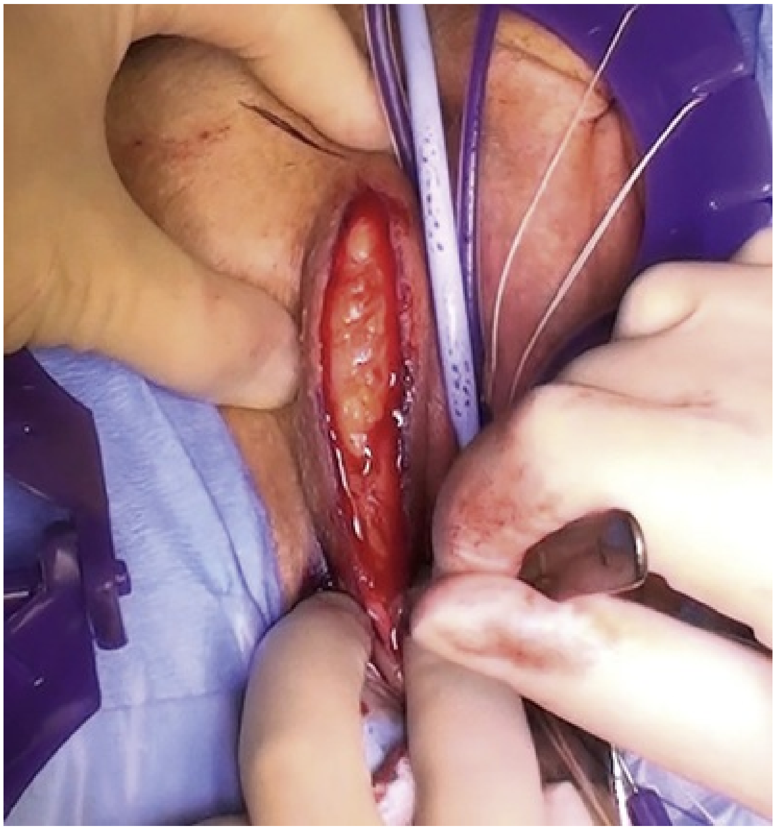

FIG. 129.16 Harvesting of a Martius flap. The incision is made in the labia. A large flap may be obtained (see Fig. 129.17).

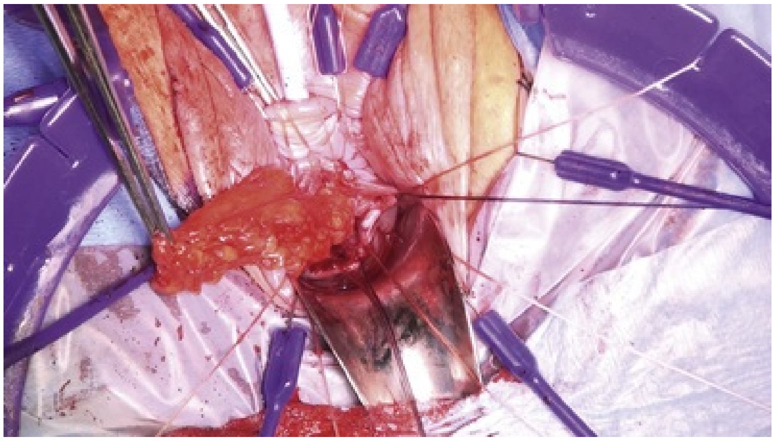

FIG. 129.17 Tunneling of the Martius flap. (From Raz S: Vesicovaginal fistulae. In Raz S, editor: *Atlas of transvaginal surgery,* Philadelphia, 1992, Saunders, p 158.)

Rangnekar et al. (2000) reported on the usefulness of the Martius flap in urethrovaginal fistulae and VVFs, the majority of which (32 of 46) were a result of obstetric trauma (Rangnekar et al., 2000). Of the VVF repairs, 4 of 21 repairs without a Martius flap failed, compared with none of the 13 procedures that included an adjuvant Martius flap. Eilber et al. (2003) reported that 33 of 34 (97%) patients undergoing repair of a distal VVF with a Martius flap were cured after the first operation.

For posthysterectomy fistulae, the distance from the labial harvesting site of the Martius flap to the fistula at the apex of the vagina may be considerable. Mobilizing and then tunneling the Martius flap to reach this location may compromise its blood supply and viability. In these cases, a peritoneal flap can be used (Raz et al., 1993).

Peritoneal Flap.

The use of a peritoneal flap during transvaginal repair of a complex VVF is a simple procedure that does not require extravaginal harvesting of the flap. **This technique is used primarily in conjunction with repair of a high-lying posthysterectomy VVF** (Eilber et al., 2003; Raz et al., 1993). Notably, peritoneal flaps may also be used as an adjunctive measure during transabdominal repair of VVF, although the approach and technique are vastly different (Chen, 1981; Eisen et al., 1974; Lentz, 2005).

After a two-layer closure as described previously, the peritoneum is identified posteriorly. The peritoneum and preperitoneal fat are identified, isolated, and mobilized from the caudal origin of the vaginal wall flap using sharp dissection.

Usually, dissection just beyond the posterior wall of the bladder will expose the edge of the peritoneum in the anterior cul-de-sac (Raz et al., 1993). The peritoneum is identified as a distinct layer from the bladder. The peritoneum is not opened but is mobilized and then advanced over the fistula repair and secured with interrupted absorbable sutures in a tension-free manner (Fig. 129.18). If a peritoneotomy is made during dissection or mobilization, the peritoneal defect can be closed as the flap is secured to the perivesical fascia over the fistula repair. The vaginal flap is then advanced and closed as previously described.

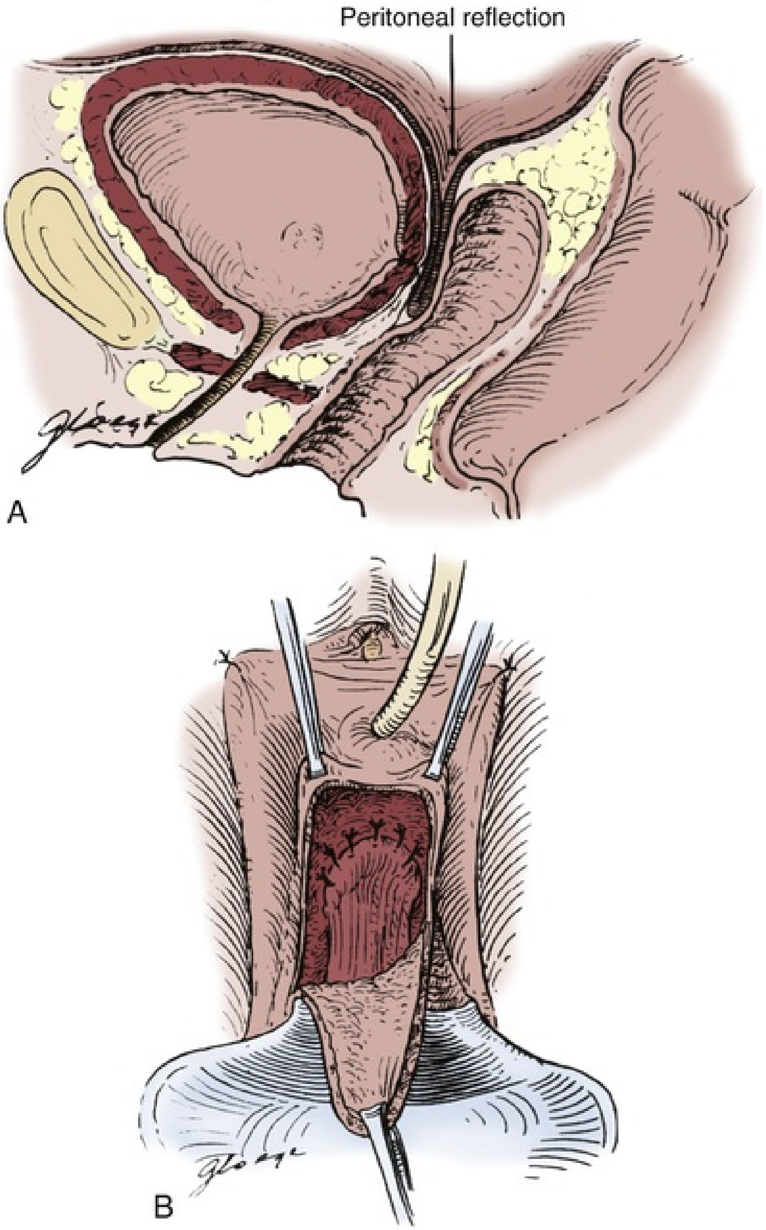

FIG. 129.18 Peritoneal flap. (A) Diagrammatic representation of the location of the peritoneal flap during vesicovaginal fistula repair. (B) Diagram of peritoneal flap advanced over fistula repair. (A and B, From Raz S: Fistulae: transvaginal repair of vesicovaginal and urethrovaginal fistulae. In Raz S, editor: *Atlas of transvaginal surgery*, ed 2, Philadelphia, 2002, Saunders, p 242.)

Greater Omentum.

The omentum is a particularly useful structure in the repair of VVF. **Although most commonly used as an adjunct during transabdominal VVF repair (an**

interpositional layer between the bladder and vagina), it has occasional usefulness in transvaginal VVF repair, if it had been brought down into the pelvis during a prior surgical procedure. **Favorable properties of the omentum include its ability to be mobilized on a well-vascularized pedicle into the deep pelvis without tension, its inherent lymphatic properties, its ability to contribute to healing even in the presence of infection, and the ease with which epithelialization occurs on its surface** (Turner-Warwick, 1975; Wein et al., 1980).

The use of interposition material is controversial and clear guidance cannot be given. There are no prospective RCTs and the case series only represent the author's personal experiences. Several authors advocate the use of several interposition materials (omentum, Martius flap, buccal mucosa, peritoneum) in open, vaginal, laparoscopic, and robotic repairs (Chen, 1981; Javed et al., 2015; Mahdy, 2014; Malde et al., 2017; Singh et al., 2013; Tobias-Machado et al., 2014; Watts et al., 2017), whereas others showed that the interposition of tissue did not influence the outcome (Kelly et al., 2017; Martini et al., 2016; Miklos et al., 2015; Price and Price, 2016; Tebeu et al., 2012; Wahab et al., 2016).

Other Flap and Graft Techniques.

A variety of flaps including gracilis muscle flaps (Izes et al., 1992), labial myocutaneous flaps (Symmonds and Hill, 1978), seromuscular intestinal flaps (Mraz and Sutory, 1994), and rectus abdominis flaps (Menchaca et al., 1990) have been used as adjunctive measures in the repair of complex VVF. Obstetric fistulae associated with significant urethral loss may be repaired, in part, with the use of anterior or posterior bladder flaps (Elkins, 1994; Hanash and Sieck, 1983; Khanna, 1992). The gracilis muscle in the medial thigh is a convenient adjunct to repair large soft-tissue defects, especially those associated with radiation therapy (Heckler et al., 1980; Obrink and Bunne, 1978). The gracilis muscle is in proximity to the vagina and has a reliable blood supply. The muscle is mobilized through a thigh incision from its distal attachment on the tibial condyle, with care taken to preserve its blood supply. It is tunneled cephalad into the vagina subcutaneously and secured over the fistula. Bilateral gracilis muscle flaps can be used for total vaginal reconstruction (Fig. 129.19).

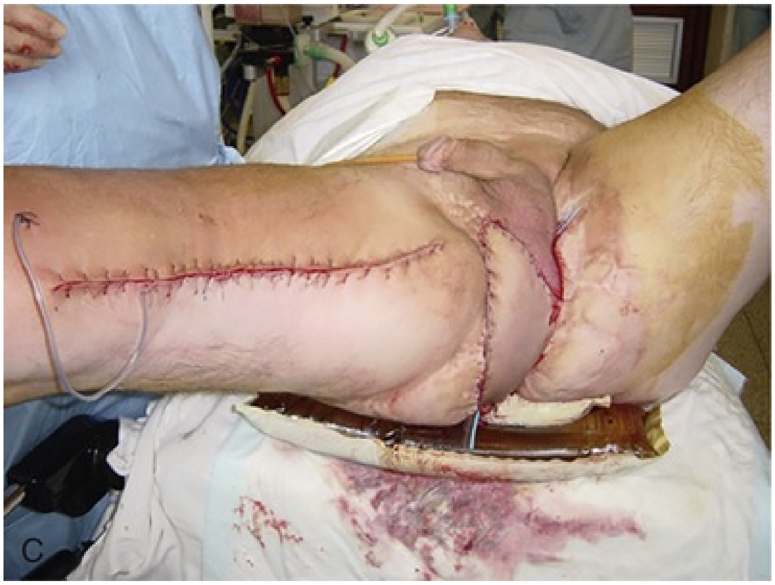

FIG. 129.19 (A) Large perineal defect. (B) Harvesting of a pedicled musculocutaneous gracilis flap that can be used to close perineal wounds after fistula repair. Can also be harvested as a pedicled muscular flap if the skin defect of the acceptor site can be closed easily. (C) Closure of the perineal wound by gracilis musculocutaneous flap. (Courtesy Professor AR Mundy, UCLH, London, UK.)

Bladder mucosa as a free graft has been used for repair of VVF (Brandt et al., 1998; Ostad et al., 1998; Fig. 129.20). The bladder is approached extraperitoneally and a small cystotomy is performed. The fistula tract is identified and denuded of mucosa circumferentially for approximately 1 cm. A free graft of bladder mucosa is harvested from the edge of the cystotomy and placed over the denuded VVF tract and secured in place with absorbable suture. Brandt et al. (1998) reported a 96.3% success rate in 80 patients. Ostad et al. (1998) reported on 6 patients with complex, high, irradiated, large or recurrent VVF, all of whom were cured by this technique. Buccal mucosa has been used as interposition material in 2 recurrent fistulae (Hadzi-Djokic et al., 2015).

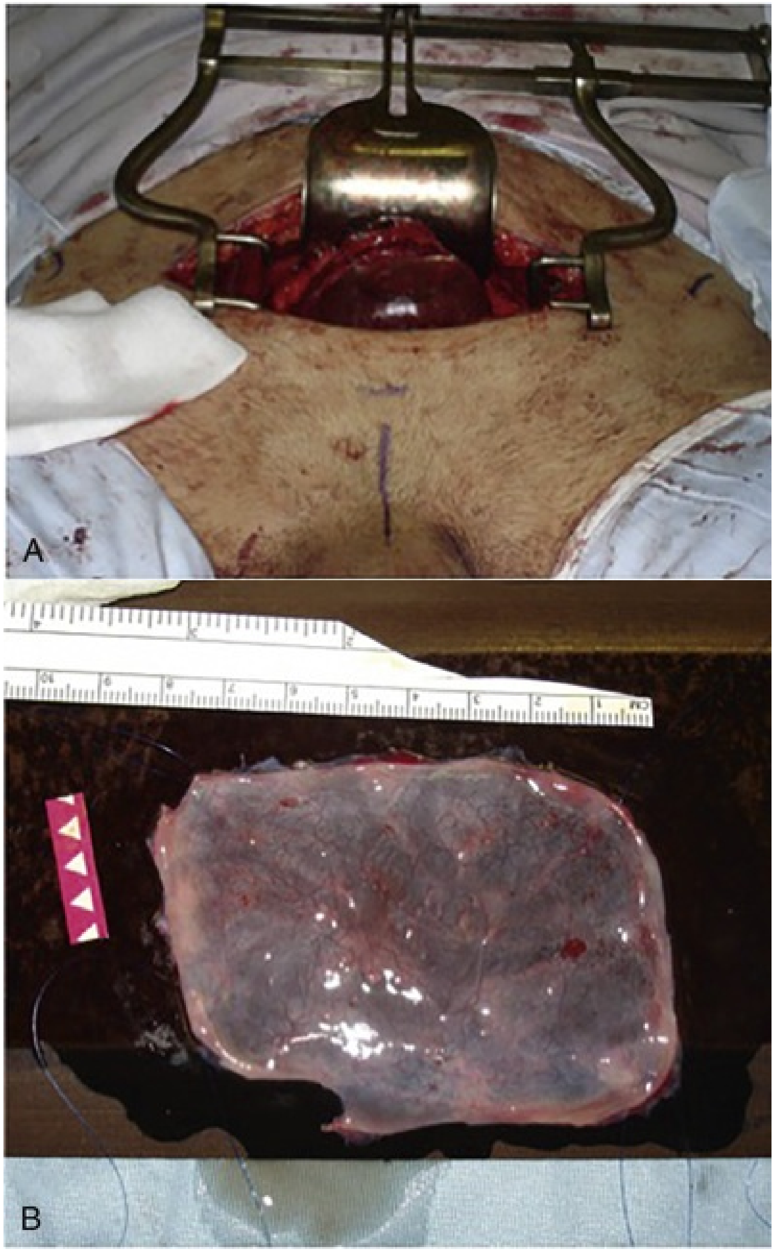

FIG. 129.20 (A) Bladder mucosal flap harvested by open detrusorectomy. (B) Bladder mucosa spread out, ready to be used as free flap. (Courtesy PCB Anderson, Russell's Hall Hospital, Dudley, UK.)

Vesicovaginal Fistulae and Urinary Diversion.

In some patients, repair of VVF is not possible or multiple surgical attempts have failed. This is probably most commonly associated with existing pelvic malignancy, severe radiation damage, and/or large soft-tissue loss, especially in the setting of obstetric fistula. However, some patients may simply not be candidates for repair because of coexistent medical morbidities, making them a prohibitive surgical risk. **In the former group, urinary diversion in the form of either a urinary conduit** (Kisner and Kesner, 1987) **or a continent reservoir can be considered. Fistulae in patients who are not candidates for surgical intervention may be managed by percutaneous ureteral occlusion and permanent nephrostomy** (Amsellem-Ouazana et al., 2006; Boudghene et al., 1988; Farrell et al., 1997; Franke et al., 2015; Hubner et al., 1992; Kim et al., 2008; Papanicolaou et al., 1985).

In the developing world, where catheters and ostomy appliances are either too expensive or completely unavailable, continent urinary diversion or incontinent urostomies are often not practical, which presents ethical issues with the alternative treatments (Arrowsmith, 2007; Wall et al., 2008). In these situations, internal urinary diversion with ureterosigmoidostomy has some application in patients with unreconstructable lower urinary tracts (El-Lamie, 2001; Kontturi and Larmi, 1972; Lassey et al., 2002; Lentz and Homesley, 1995; Mayer, 1951; Radopoulos et al., 2008). This is clearly a last-resort operation because of its significant metabolic and neoplastic potential.

Outcomes of Vesicovaginal Fistula Repair

The success rate reported for a simple VVF repair in the modern era, whether through an abdominal or vaginal approach, is in excess of 85%. Long-term follow-up suggests that the majority of patients are greatly improved, although minimally bothersome symptoms may persist in a minority of patients over the long term, causing little impact on quality of life (Dolan et al., 2008). Complicated VVFs including those resulting from obstetric causes, larger fistulae, and those associated with radiation therapy generally have lower success rates or have persisting (stress) incontinence despite a closed fistula (Alling Møller et al., 2000; Hillary et al., 2016; Hood, 2016; Karp et al., 2017; Loposso et al., 2016; Naidoo et al., 2017, Ouedraogo et al., 2018a; Raassen et al., 2017; Reisenauer, 2017; Tatar et al., 2017; Wall and Arrowsmith, 2007). Hillary et al. (2016) showed, in a systematic review of patients undergoing repairs in well-resourced countries, that the median overall closure rate was 94.6%, whereas in low-resourced countries this was 87.0%. Closure was significantly more likely to be achieved using a transvaginal approach than a transabdominal technique (90.8% success vs. 83.9%, Fisher's exact test; $P = 0.0176$) (Hillary et al., 2016). **In patients with obstetric fistulae associated with loss of the bladder neck and proximal urethra, relatively high rates of persistent severe sphincteric incontinence are noted despite successful**

repair of the VVF (Browning, 2004, 2006), **and this type of fistula is involved in the majority of treatment failures** (Frajzyngier et al., 2013; Goh et al., 2008). Thus despite a technically successful VVF repair, functionally, from the patient's perspective, some of these individuals may not be significantly improved after the repair because of severe stress urinary incontinence (SUI). Pubovaginal slings and periurethral injectable agents are often beneficial in these patients once the VVF has been surgically closed (Arrowsmith, 1994; Browning, 2004). In the developing world, access to synthetic mid-urethral slings is limited. Furthermore, the safety of using such materials in the setting of extensive reconstruction, such as that after repair of an obstetric fistula, is not established.

Key Points: Vesicovaginal Fistulae

- VVF is the most common acquired fistula of the urinary tract.
- In the industrialized world, surgical injury to the bladder is the most common cause of VVF, most commonly seen after hysterectomy. In the developing world, VVF is most commonly related to complications from obstructed labor.
- VVFs caused by radiation therapy are usually complex.
- VVF occurring in the setting of a history of pelvic malignancy should undergo biopsy before repair to exclude recurrent malignancy as a cause of the fistula.
- Diagnosis of VVF can be confirmed on CT, MRI, and VCUG.
- Upper tract imaging is obtained after a diagnosis of VVF to exclude injury to the ureter(s).
- Small, oblique fistulae may respond to conservative therapy, including prolonged urinary catheterization with or without fulguration of the fistula tract.
- There is no optimal method for the surgical repair of all VVFs. In the properly selected patient, transabdominal and transvaginal approaches to fistula repair have similar success rates. Laparoscopic and robotic approaches for VVF repair are advancing the field. Adjuvant tissue flaps may be useful to prevent surgical failure in the setting of complex or recurrent fistula, radiation fistula, obstetric fistula, and fistulae with tenuous repairs.

Ureteric Fistulae

Etiology and Presentation

Ureteral fistulae to the genital tract in the female most often connect with the vagina but have also been reported to connect with other genital structures, including the fallopian tube or uterus (Billmeyer et al., 2001; Crochet et al., 2008). **Risk factors for the development of ureterovaginal fistulae (Box 129.4) include endometriosis, obesity, pelvic inflammatory disease, radiation therapy, and pelvic malignancy** (Brandes et al., 2004; Drake and Noble, 1998; Leonard et al., 2007; Mteta et al., 2006). A large prospective case series from Finland found an incidence of ureteric injury associated with hysterectomy for benign pathology of 0.2% (10/5279) with the lowest rate associated with vaginal hysterectomy and no difference between open and laparoscopic abdominal hysterectomy (Brummer, 2011). The incidence of immediate and delayed ureteric injury during radical hysterectomy was found to be 1.3% (7/536) and 2.4% (13/536), respectively, in a series from Serbia; injuries appeared more common after prolonged surgery and in patients with diabetes, obesity, or wound infection (Likic, 2008). A registry study from the United States found an overall incidence of ureteric injury during radical hysterectomy of 0.8% (Frankman, 2010). Case series from referral centers in India, Pakistan, and Egypt showed that the proportion of urinary tract injuries resulting from obstetric or gynecologic surgical trauma that primarily affected the ureter varied from 1% to 23% (El-Tabey, 2011; Kumar et al., 2009; Nawaz, 2010; Sachdev, 2009).

Box 129.4

Cause of Ureterovaginal Fistulae

Gynecologic Surgery

Abdominal hysterectomy
Vaginal hysterectomy
Radical hysterectomy
Cesarean section
Anterior colporrhaphy (cystocele repair)

Other Pelvic Surgical Procedures

- Vascular surgery
- Urologic surgery including retropubic bladder neck suspensions
- Colon surgery

Other Causes

- Locally advanced malignancy
- Radiation therapy
- Pelvic trauma
- Chronic inflammatory diseases (e.g., actinomycosis)

Ureteric fistulae can also occur as a consequence of open and laparoscopic endometriosis or colorectal surgery (Alves et al., 2017; Chang et al., 2016).

Ureteroarterial fistulae are uncommon but can be life threatening because of massive bleeding in the ureter (see later). They have a high mortality rate (Melegari et al., 2016). Predisposing factors are radiation therapy, vascular pathology and/or ureteral stenting. Das et al. (2016) reviewed the literature and found 61 cases. In terms of treatment, endovascular stenting has emerged as an appealing initial modality and should be considered in stable patients with less favorable candidacy for open surgical intervention secondary to pre-existing comorbidities (Das et al., 2016).

The mechanism of injury resulting in iatrogenic postoperative ureterovaginal fistulae includes ureteral laceration or transection, blunt avulsion, crush injury, partial or complete suture ligation, and, finally, ischemia caused by operative devitalization of the ureteral vascular supply and/or cautery injury. Overall, the ureter is most commonly injured during gynecologic surgery in the distal one-third or pelvic portion, which is, accordingly, the only location at which a ureteral injury may result in a ureterovaginal fistula. Not uncommonly this occurs inadvertently during an attempt by the surgeon to control active bleeding using clamps or suture ligation of large tissue segments in the deep pelvis.

The pelvic ureter is intimately related to the female genital tract throughout its course. **In the deep pelvis, the ureter passes at the lateral edge of the uterosacral ligament and ventral to the uterine artery and then passes just lateral to the cervix and fornix of the vagina.** In close apposition to these structures, the ureter must be carefully avoided during any gynecologic procedure in the deep pelvis. **Any injury to the ureter that exposes the ureteral lumen (i.e., laceration) or results in delayed necrosis of a portion of the ureter (i.e., suture ligation) and subsequent urinary extravasation may lead to a fistula.** A ureterovaginal fistula may result from a sequence of events, including urinary extravasation from the ureteral injury, urinoma formation, subsequent extension along non-anatomic planes created during surgery, and eventual drainage through the vaginal incision or an ischemic area of the vaginal cuff. Infection, prior radiation therapy, or other factors that may impede healing probably promote the development of ureterovaginal fistulae under these circumstances.

The most common presenting symptom is the onset of constant urinary incontinence 1 to 4 weeks after surgery (Mandal et al., 1990). This may have been preceded by several days of flank or abdominal pain, nausea, and low-grade fever, presumably as a result of urinoma and/or obstruction of the kidney (Lee et al., 1988). Flank pain will often be masked in the postoperative period because of the use of postoperative narcotic analgesics. **Of importance, and in direct contrast to VVF, in the setting of continuous urine leakage from a ureterovaginal fistula, patients will continue to report normal voiding habits because bladder filling is maintained from the contralateral, presumably undamaged, upper urinary tract.**

Prevention of this type of fistula is usually done by preventive stenting of the ureters. A randomized study involving 3141 women undergoing open or laparoscopic gynecologic surgery lasting for longer than 30 minutes found that the incidence of ureteral injury after prophylactic insertion of ureteral stents (1.2%) was similar to controls (1.1%) (Chou et al., 2009). A previous cost analysis from the US perspective suggested that stenting was worthwhile only if the risk of injury was higher than 3.2% (Schimpf et al., 2008). If injury does occur, many cases, even those involving bilateral injury, can be managed by endoscopic techniques.

Diagnosis and Management

Unfortunately, intraoperative diagnosis of a GU or GI injury is made in only about half of the cases that result in fistula (Ostrzenski Ostrzenska, 1998). In one study, 36% of VVFs were found within 1 week of a laparoscopic hysterectomy and 50% in the second week. Most patients who had undergone transabdominal hysterectomies had leakage in the second week (90%) (Kochakarn and Pummangura, 2007).

Diagnosis and confirmation of a ureterovaginal fistula can usually be accomplished with a combination of a relevant history, physical examination, and appropriate radiologic studies, including cross-sectional imaging (such as a CT urogram), IVU, and retrograde pyelography (Mandal et al., 1990; Fig. 129.21). Urine may extravasate externally or internally. Creatinine levels in the urine are higher than serum levels. Therefore, in the setting of a suspected fistula, testing the creatinine level in either the extravasated fluid or the accumulated ascites and comparing this value to the serum creatinine levels will confirm urinary leakage but not the location of the fistula. Likewise, testing potassium levels will show higher levels compared with serum levels.

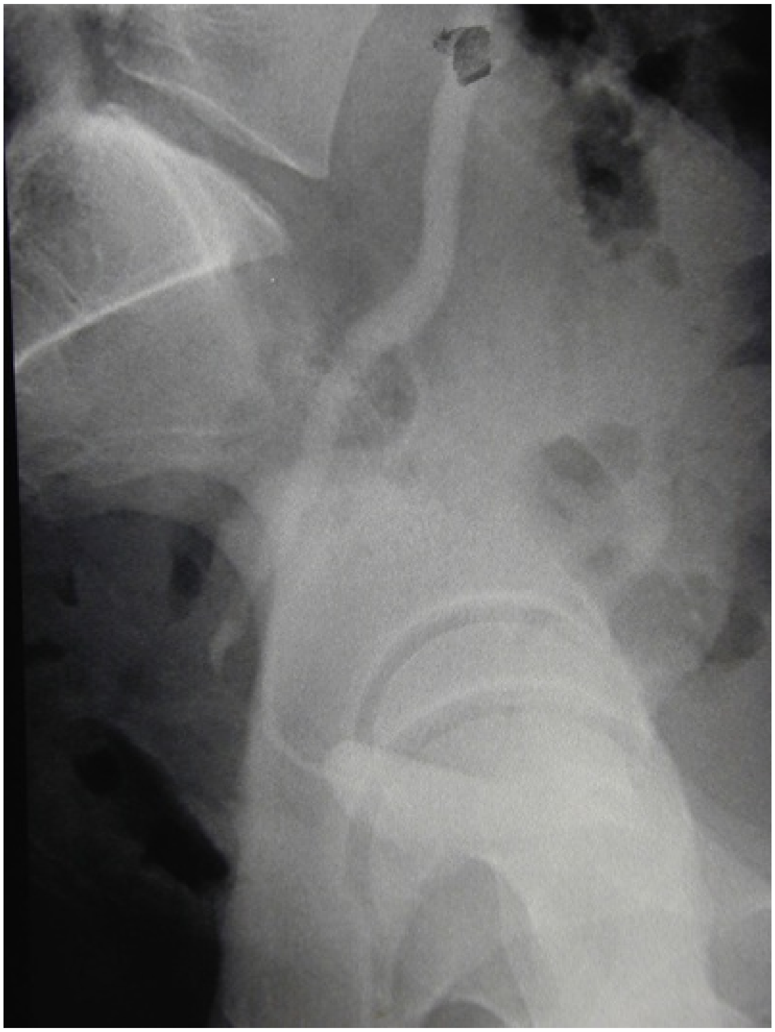

FIG. 129.21 Diagnosis of ureterovaginal fistula. Retrograde pyelogram

demonstrates a distal ureteral stricture with a small fistula tract with contrast in the vagina superimposed on contrast in the bladder from the contralateral retrograde ureterogram.

A double dye test may be of some value in differentiating between a ureterovaginal fistula and VVF as a cause of ongoing urinary leakage (Raghavaiah, 1974). Suspicion of a ureterovaginal fistula should prompt upper tract imaging (Badenoch et al., 1987). **The IVU or CT urogram most commonly will demonstrate some degree of ureteral obstruction and associated caliectasis or ureteral dilation** (Selzman et al., 1995). **These findings in the presence of constant vaginal drainage strongly suggest a ureterovaginal fistula.** Alternatively, if the fistula is mature and large, the upper urinary tract may appear completely unremarkable; however, urine will be seen opacifying the vagina before the postvoid image (Fig. 129.22). Antegrade pyelography after nephrostomy tube decompression of a partially obstructed ureter may be associated with similar findings (Fig. 129.23). **A high oblique or lateral film may be necessary to differentiate the contrast in the bladder from that in the vagina.** A retrograde pyelogram may show the ureter and fistula well or may demonstrate an abrupt termination of the ureter 2 to 4 cm from the ureteric orifice. **If retrograde pyelography demonstrates the fistula, as well as ureteral continuity, then an attempt at stenting is warranted. Cystography is performed primarily to exclude a coexistent VVF.** A cystogram will not demonstrate the ureterovaginal fistula unless there is preexisting vesicoureteral reflux. Ureterovaginal fistulae may be seen on CT urography or MRI (Fig. 129.24); however, an additional role for such cross-sectional imaging is to evaluate for an associated pelvic abscess or undrained urinoma. An unstructured review by Narayanan et al. (2009) suggested that MRI, particularly with T2 weighting, provided optimal diagnostic information regarding fistula associated with pelvic malignancy, with contrast-enhanced CT with late excretory phase an acceptable alternative. These newer modalities were considered to be superior to other x-ray contrast techniques and ultrasonography. MRI is also used more widely (Abou-El-Ghar et al., 2012).

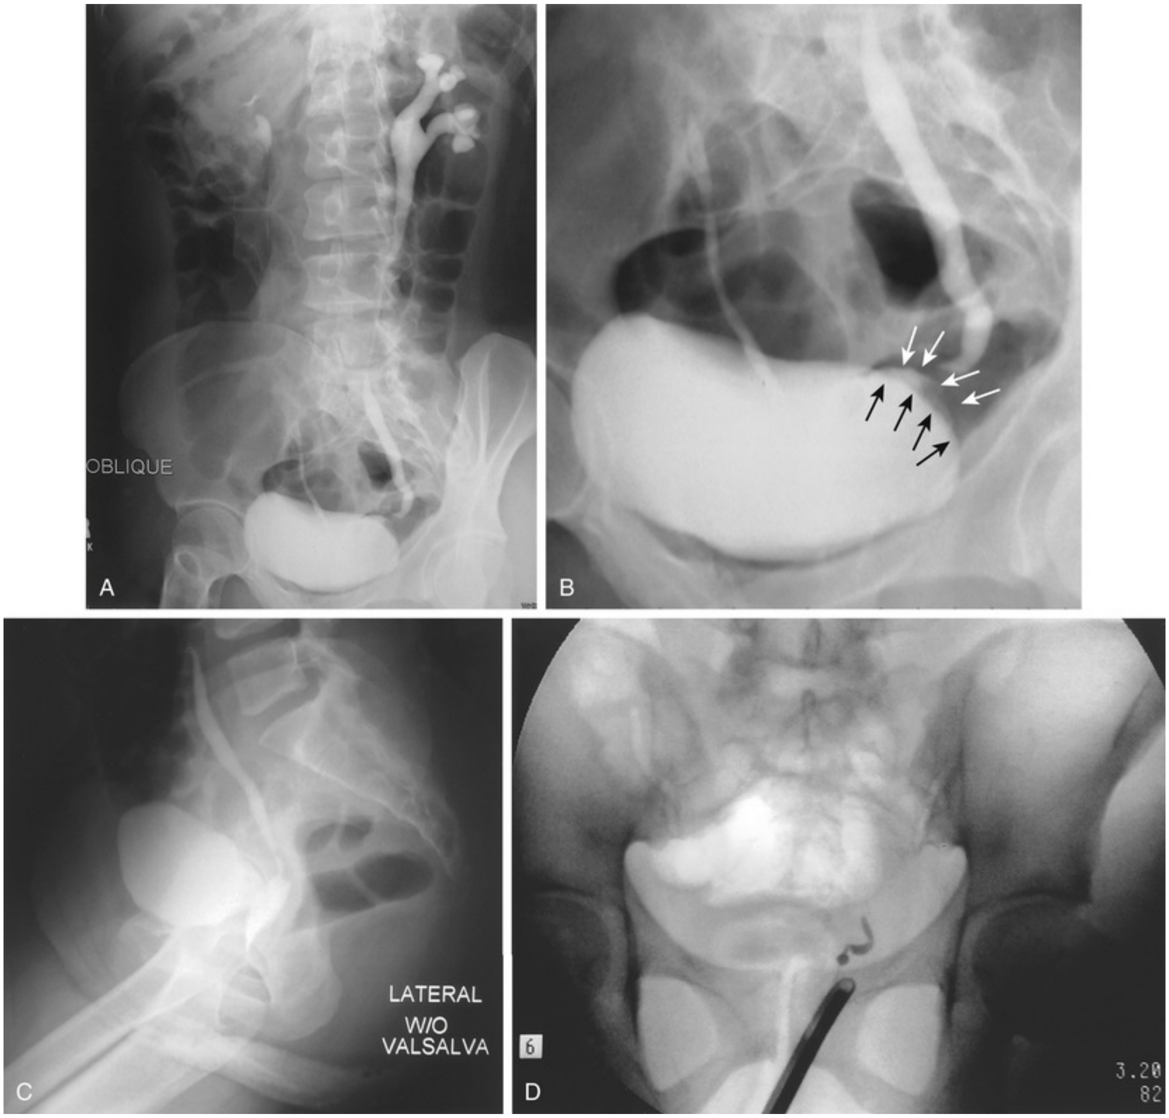

FIG. 129.22 Ureterovaginal fistula. (A) Oblique view on intravenous urography shows mild left-sided hydroureteronephrosis associated with a distal tapering of the ureter. (B) Faint and subtle opacification of the vagina *(white arrows)* is somewhat obscured by bladder filling (bladder edge indicated by *black arrows*) on this oblique image. (C) Lateral view demonstrates the ureter clearly entering the vagina. (D) Retrograde pyelogram demonstrates abrupt termination of the distal ureter.

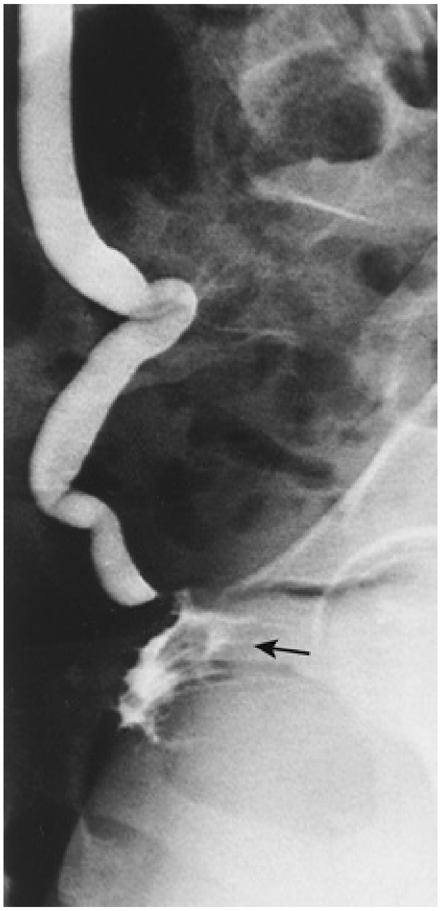

FIG. 129.23 Ureterovaginal fistula. Antegrade nephrostogram demonstrates mild ureterectasis with opacification of the vagina *(arrow).*

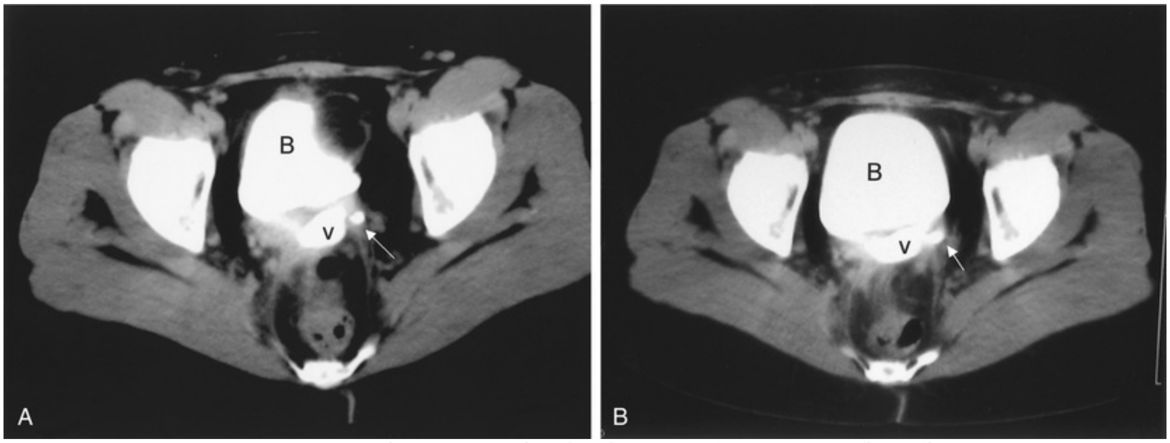

FIG. 129.24 Computed tomography (CT) scan of ureterovaginal fistula. (A) CT scan demonstrates contrast material within the bladder *(B)* and vagina *(v).* The ureter is visible *(arrow)* adjacent to the vagina. (B) This image shows the ureter *(arrow)* entering the vagina.

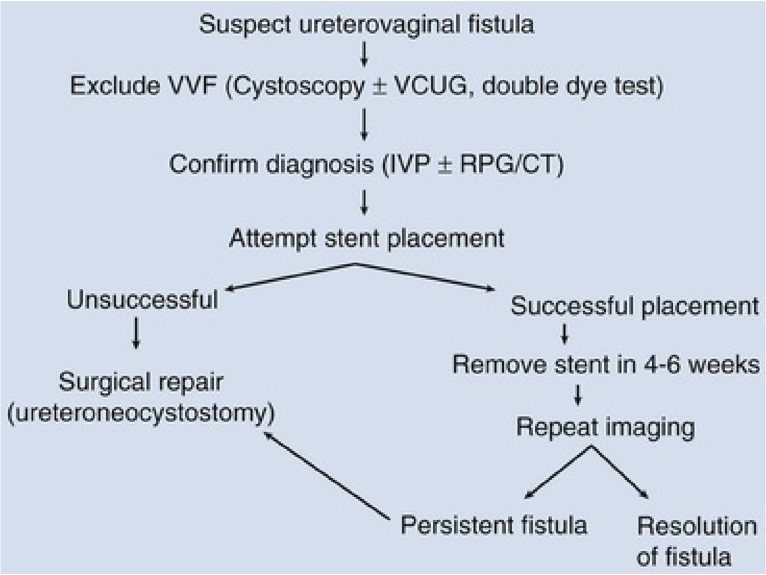
The goal of therapy is the expeditious resolution of urinary leakage, avoidance of urosepsis, and preservation of renal function. Once the diagnosis is made, prompt drainage of the affected upper urinary tract is essential (Gerber and Schoenberg, 1993), **because partial ureteral obstruction is often present.** An attempt at ureteral stenting or percutaneous nephrostomy tube decompression is warranted as soon as possible (Dowling et al., 1986) if direct open surgical repair is not immediately considered. Occasionally, conservative, nonoperative management alone will result in fistula closure in patients with ureteral continuity and a normal-appearing ureter beyond the fistula (Alonso Gorrea et al., 1985), although this is unusual. Endoscopic management, including ureteral stenting, may be sufficient to promote closure of the fistula in some cases. The use of ureteric stenting in patients with ureterovaginal fistulae was reported in 11 studies, including 126 patients in total (Andriole et al., 1984; Barton et al., 1992; Beaghler et al., 1997; Campbell et al., 1993; Dowling et al., 1986; Koonings et al., 1992; Lang, 1984; Lingeman et al., 1995; Mandal et al., 1990; Narang et al., 2007; Ustunsoz et al., 2008); this resulted in closure in 63 cases altogether. Success rates were between 6% and 100%, although the overall closure rate across all series is calculated at 50% ± 18%.

Where retrograde stenting proves impossible, percutaneous nephrostomy and antegrade stenting may be considered if there is some degree of pelvicalyceal dilatation. Ureteroscopy may also be helpful (Koonings et al., 1992; Narang et al., 2007), and a technique for combined antegrade and retrograde ureteroscopic cannulation has been reported (Beaghler et al., 1997). In one report all cases of ureterovaginal fistula were managed by temporary diversion using a percutaneous nephrostomy followed by delayed repair 4 to 6 weeks later (Onuora et al., 1993), and a similar approach was taken in the management of one ureterouterine fistula (Wang and Hung, 1997).

If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, re-implantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. Recent case series suggest that this standard surgery can be performed safely and with reasonable operative times using laparoscopic or robotic techniques if the relevant skills and facilities are available (Laungani, 2008; Modi, 2008; Puntambekar, 2006). A recent case report has suggested that open repair through the vagina is possible if abdominal access is problematic (Chen, 2007).

If ureteral stenting is unsuccessful because of complete ureteral occlusion

or if prolonged leakage persists despite stenting, then formal surgical repair is indicated (Fig. 129.25). **Timing of the repair of ureterovaginal fistulae is controversial.** Some authors advocate early repair (Pal et al., 2016; Sakellariou et al., 2002; Yu et al., 2013), whereas others recommend a delay of 4 to 8 weeks (Demirci et al., 2013). More recent literature suggests that early repair is preferred and is not associated with an increase in morbidity or higher failure rates, if the damage is not too severe (Drake and Noble, 1998; Hampel et al., 2015).



Suspect ureterovaginal fistula
Exclude VVF (Cystoscopy ± VCUG, double dye test)
Confirm diagnosis (IVP ± RPG/CT)
Attempt stent placement
Unsuccessful
Surgical repair (ureteroneocystostomy)
Successful placement
Remove stent in 4-6 weeks
Repeat imaging
Persistent fistula
Resolution of fistula

FIG. 129.25 Algorithm for diagnosis and management of ureterovaginal fistula. *CT,* Computed tomography; *IVP,* intravenous pyelography; *RPG,* retrograde pyelography; *VCUG,* voiding cystourethrography; *VVF,* vesicovaginal fistula.

As noted previously, ureterovaginal fistulae most commonly result from injury to the distal one-third of the ureter below the level of the iliac vessels. **The usual site of the injury in the very distal ureter and the surrounding fibrosis and inflammation usually preclude primary repair of the fistula. Therefore open surgical repair most commonly involves ureteroneocystostomy.** The ureter is located and dissected as distally as possible in the pelvis. Care is taken to preserve the periureteral adventitial layer to prevent ureteral ischemia. The ureter is divided distally, and a ureteroneocystostomy is performed with or without a psoas hitch. It is not important to create a tunneled anastomosis. Occasionally a Boari flap or replacement with bowel segments (with or without reconfiguration) may be necessary because of extensive ureteral injury. **Robotic and**

laparoscopic repairs using the same principles as open repair have been reported (Miklos et al., 2015; Modi et al., 2006; Watts et al., 2017), **with the potential benefits of shorter hospitalization and quicker convalescence.** Rarely, transureteroureterostomy, ileal substitution of the ureter, or renal autotransplantation is required. In patients with a normal contralateral kidney in whom there is extensive renal damage because of obstruction or infection, nephrectomy may be the most expeditious method of management.

Successful repair of ureterovaginal fistulae is expected in more than 90% of cases. Blandy et al. (1991) reported on early repair of iatrogenic injury to the ureter in 43 cases including 30 ureterovaginal fistulae. All patients were cured using a combination of techniques including the Boari flap.

Ureteral fistulae to other gynecologic organs have been reported. Ureterouterine fistulae may occur as a result of cesarean section, uterine malignancy, and elective abortion (Billmeyer et al., 2001; Lo et al., 2016). Uretero–fallopian tube fistulae have also been reported as a consequence of laparoscopic fulguration of endometriosis (Chene et al., 2015; Crochet et al., 2008; Ingber et al., 2010).

Key Points: Ureterovaginal Fistulae

- Ureterovaginal fistulae occur more commonly after benign hysterectomy than after radical hysterectomy.
- Patients have constant urinary leakage but usually a normal voiding pattern.
- In the setting of ureteral patency, a trial of an indwelling ureteral stent may result in resolution of the fistula.
- If conservative management fails or if there is complete obstruction of the distal ureter, then ureteral reimplantation with or without a psoas hitch is usually curative.

Vesicouterine Fistulae

Etiology and Presentation

Vesicouterine fistulae are among the least common urogynecologic fistulae (Benchekroun et al., 1999; Tancer, 1986). However, the incidence of this condition is increasing in parallel with the rising numbers of low-segment cesarean sections being done worldwide (Kumar et al., 1988; Porcaro et al., 2002). **Cesarean section is by far the most common cause of this unusual fistula** (Tancer, 1986). Tancer related that of the 74 cases of vesicouterine fistulae reported from 1947 to 1986, 57 followed low-segment cesarean section, 7 followed vaginal operative delivery, and the remaining cases were related to a variety of disparate scenarios, including induced abortion, hysterectomy, and dilation and curettage (D&C). Jozwik et al. (1998) reported that 21 of 24 vesicouterine fistulae treated over a 12-year period occurred after cesarean section, the majority of which were repeat cesarean sections. Those undergoing vaginal birth after prior cesarean section (VBAC) are also at risk for vesicouterine fistula (Gil and Sultana, 2001). Vesicouterine fistulae may occur spontaneously as a result of a ruptured uterus during obstructed labor. In these cases, the posterior bladder wall may tear along the uterine rupture line creating the potential for a fistula. Bladder wall invasion by chorionic villi penetrating beyond the uterine serosa, placenta percreta, may also create a vesicouterine fistula (Krysiewicz et al., 1988). A foreign body such as an intrauterine device (IUD) (Schwartzwald et al., 1986), uterine artery embolization (Sultana et al., 2002), brachytherapy (Memon et al., 1998), traumatic bladder catheterization (Futter and Baker, 1995), Meyer-Rokitansky syndrome (Okusanya and Garba, 2010), and endometrial ablation (Rooney and Cholhan, 2010) have been reported to cause vesicouterine fistula. **In most cases, simultaneous injury to the bladder and uterus is the inciting event.** An unrecognized and unrepaired (occult) bladder injury, or incorporation of a portion of the bladder during closure of the uterus during any number of operations, may result in a vesicouterine fistula. **Anatomically, the most common location of the fistula is along the posterior bladder wall in the midline, or from the genital side, just cephalad to the internal cervical os.**

Unlike other types of urogynecologic fistulae, vesicouterine fistulae may or may not manifest with constant urinary incontinence because of the

sphincter-like activity of the cervix; the exception is in the setting of an incompetent cervix, wherein urinary leakage is constant. In this clinical setting, which typically occurs after vaginal delivery, urine flows from the bladder through the fistula into the uterine cavity and then into the vagina through an incompetent cervical os. However, in the setting of a relevant clinical history, vesicouterine fistulae also manifest with menouria and cyclic hematuria in the setting of urinary continence. **Youssef syndrome describes the presenting symptom complex of vesicouterine fistula: menouria, cyclic hematuria with associated apparent amenorrhea, infertility, and urinary *continence*** (Youssef, 1957) **in a patient who has undergone prior low-segment cesarean section.** Endometriosis of the bladder in which cyclic hematuria may be present must be differentiated from this condition.

Diagnosis and Management

Diagnosis of vesicouterine fistula can be made by a combination of cystoscopy and radiographic studies, although a high degree of suspicion is necessary to pursue the diagnosis if initial radiographic studies prove negative (Smayra et al., 2005). Cystoscopy may demonstrate a midline lesion along the posterior bladder wall (Fig. 129.26). Urine cytology may reveal endothelial cells. Instillation of contrast material into the bladder (cystogram) will outline the uterine cavity (Fig. 129.27), whereas a hysterosalpingogram will demonstrate filling of the bladder. MRI, CT (Fig. 129.28), and ultrasonography have been used in the diagnosis and evaluation of vesicouterine fistulae as well (Huang et al., 1996; Mercader et al., 1995; Murphy et al., 1999). IVU or contrast-enhanced CT can be used to exclude concomitant ureteral injury.

FIG. 129.27 Cystogram demonstrating vesicouterine fistula in a postpartum woman. (A) Filling of the bladder demonstrates a small amount of contrast material cephalad to the tip of the Foley catheter. The uterine cavity is faintly seen. (B) Postvoid image demonstrates filling of the uterine cavity and cervical canal. The bladder is not well demonstrated. This patient's status is immediately postpartum. Contrast material in the vagina outlines the incompetent cervical canal and os.

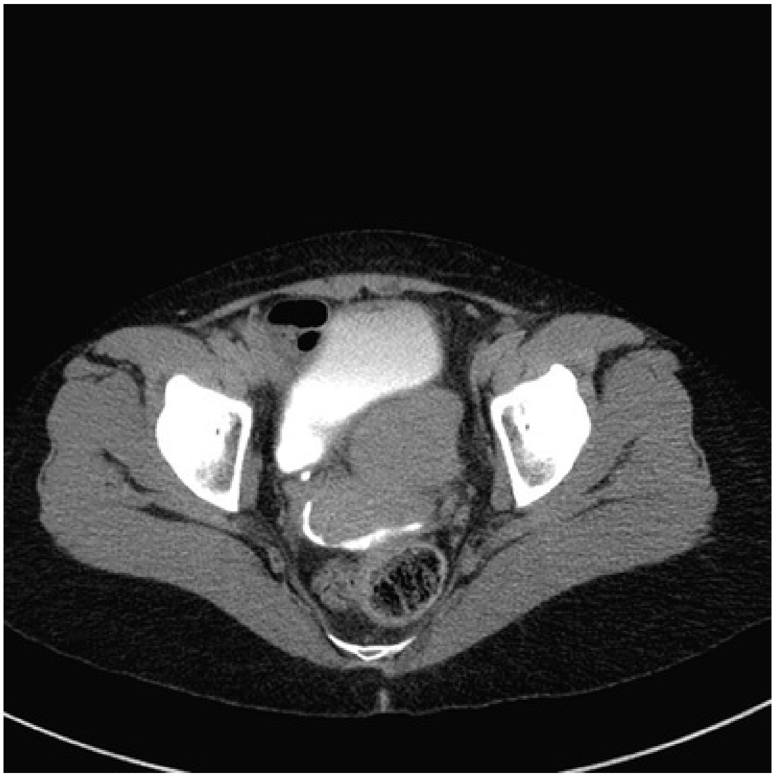

FIG. 129.28 Computed tomography scan with contrast enhancement demonstrating a vesicouterine fistula. Contrast material is layering in the partially filled urinary bladder; contrast opacification of the uterine canal suggests a vesicouterine fistula.

Several different approaches have been advocated for the treatment of vesicouterine fistulae. **Prolonged indwelling bladder catheterization or fulguration of the fistula tract followed by bladder drainage may be successful in select cases, especially in patients with small, immature fistulae** (Graziotti et al., 1978; Ravi et al., 2003; Rouzi et al., 2016). **Hormonal induction of menopause will induce involution of the puerperal uterus, and this principle has been used with some success in treating this condition as well** (Ravi et al., 2003). Jozwik and Jozwik (1999) reported successful treatment in eight of nine patients with use of hormonal manipulation.

Surgical therapy for vesicouterine fistulae is often contingent on the specific reproductive wishes of the patient, **as well as other surgical factors,** but is considered definitive therapy. Vaginal repair is feasible in selected patients, but many will require an abdominal approach (Milani et al., 2017; Rajamaheswari and Chhikara, 2013). **For the patient who desires preservation of fertility, uterine-sparing surgery can be considered.** In a manner similar to an O'Conor transabdominal VVF repair, the bladder is opened and bivalved down to the fistula tract. Careful dissection allows separation of the bladder from the uterus beyond the fistula tract. The fistula tract is excised from both structures, the uterus and bladder are closed individually, and an interpositional flap, usually omentum, is secured between the two organs (Sapmaz et al., 2003). Fertility is possible after repair of vesicouterine fistula. Lotocki et al. (1996) reported five pregnancies with four full-term deliveries in a cohort of 16 patients who had undergone uterine-sparing surgery for vesicouterine fistulae. Minimally invasive laparoscopic and robotic surgical approaches to the repair of vesicouterine fistulae have been reported (Alamoudi et al., 2017; Maioli et al., 2015). **If there is no further desire for childbearing, then transabdominal hysterectomy and bladder closure should be considered. Ureteral stents can be placed to facilitate identification of the ureters intraoperatively.** After performance of the hysterectomy, the fistula tract on the posterior bladder wall is excised and the bladder is closed primarily. An omental flap can be placed into the deep pelvis to buttress the bladder closure and separate the bladder closure from the vaginal closure to reduce the possibility of a postoperative VVF.

Key Points: Vesicouterine Fistulae

- The most common cause of vesicouterine fistulae is low-segment caesarean section.
- Vesicouterine fistulae do not always manifest with urinary incontinence.
- Nonsurgical management of vesicouterine fistulae is possible by hormonally inducing involution of the uterus with maintenance of urinary drainage.
- Management of vesicouterine fistulae is contingent on the reproductive wishes of the patient. Hysterectomy followed by repair of the bladder is indicated for the individual who no longer desires fertility. Uterine-sparing procedures can be used, and successful pregnancy is possible after vesicouterine fistula repair.

Urethrovaginal Fistulae

Etiology and Presentation

In the developing world, urethrovaginal fistulae may occur as a result of obstructed labor with or without associated VVF. In industrialized countries urethrovaginal fistulae in adults mostly have an iatrogenic cause.

In feminizing genital reconstructions in children with ambiguous genitalia and surgical repairs of cloacal malformations, urethrovaginal fistulae can occur as early or late complications (Dhabalia et al., 2009; Levitt and Pena, 2010, Levitt et al., 2011; Oguzkurt et al., 2009; Park et al., 2011). Also in transsexual adults undergoing female to male reconstruction, urethrovaginal fistulae have been reported (Hage et al., 1993).

In the surgical treatment of stress incontinence in women with bulking agents (Carlin and Klutke, 2000; Hilton, 2009) or synthetic slings several cases of urethrovaginal fistulae have been reported (Blaivas and Mekel, 2014; Estevez et al., 2010a, 2010b; Glavind and Larsen, 2001; Lee and Zimmern, 2016; Morton and Hilton, 2009; Reisenauer et al., 2007, 2014). Even conservative treatment of prolapse with pessaries can lead to the formation of fistula, if these pessaries are neglected for an extended period of time, although fistula formation after only 2 weeks of pessary use has been described (Hilton and Cromwell, 2012; Walker et al., 2011).

Trauma, including inappropriate catheterization, and foreign bodies are obvious causes of fistulae (Blaivas and Purohit, 2008; Cameron and Atiemo, 2009; Holland et al., 2001; Kobayashi et al., 2010; Liu et al., 2008; Parkhurst et al., 1981; Thrumurthy et al., 2010).

Urethral diverticulae and their surgical repair may also lead to urethrovaginal fistulae (Ben Amna et al., 2002; Ganabathi et al., 1994; Greenwell and Spilotros, 2015, Lo et al., 2017; Porpiglia et al., 2002).

Urethrovaginal fistulae have also been described in some Behçet patients with vasculitis and local necrosis of the urethrovaginal septum (Chung et al., 2005; Waidelich et al., 1994).

Irradiation complications can also result in the formation of urethrovaginal fistula (Flottorp and Inversen, 1960) (Figs. 129.29 and 129.30). **Other causes of urethrovaginal fistulae include trauma (including pelvic fracture) and vaginal neoplasms.** A final important cause in the long-term–care setting is urethral catheter erosion (Andrews and Shah, 1998; Trop and Bennett, 1992). In patients with poor sensation, especially the cognitively or otherwise neurologically impaired patient, pressure necrosis from a chronically indwelling catheter may result in traumatic hypospadias and urethrovaginal fistula. If the condition is not recognized, over time the catheter may erode to the level of the bladder neck and beyond, effectively creating a bivalved urethra and a urethrovesicovaginal fistula (Fig. 129.31). For that reason suprapubic catheters are to be preferred in patients with cognitive and/or neurologic impairment.

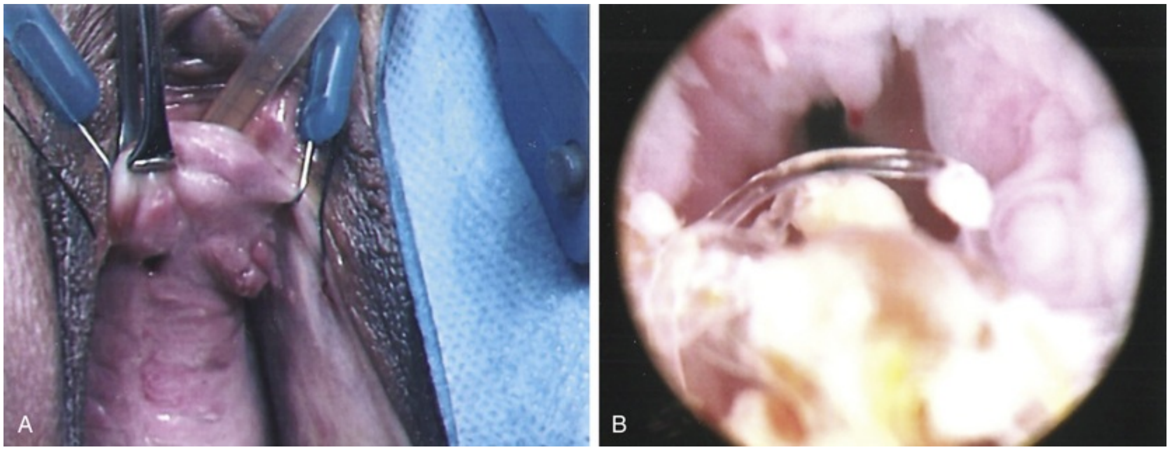

FIG. 129.29 Urethrovaginal fistula after mid-urethral synthetic sling procedure. (A) Intraoperative view demonstrating a urethrovaginal fistula at the bladder neck after a mid-urethral sling procedure. (B) Cystoscopy demonstrates intraurethral sling material with calcified material.

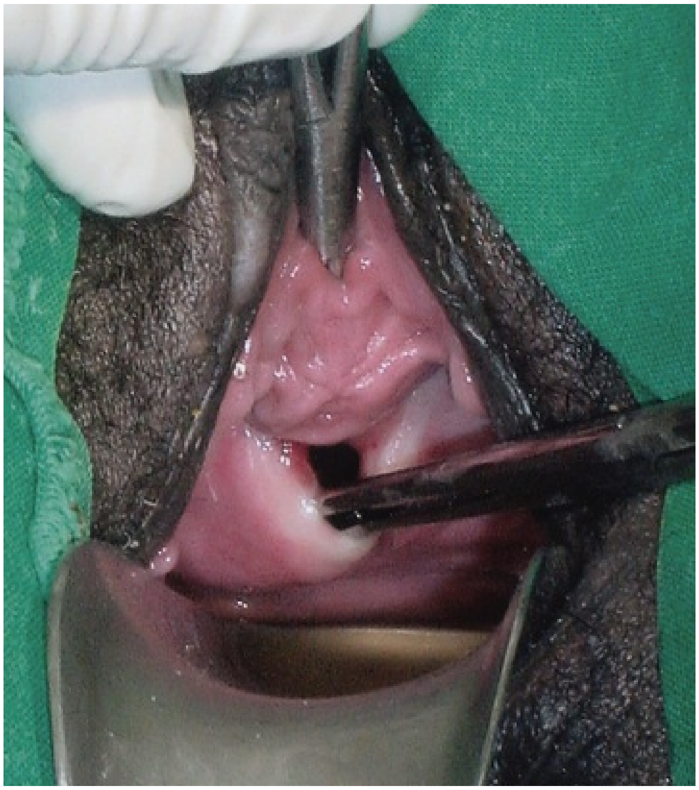

FIG. 129.30 Urethrovaginal fistula at the bladder neck from obstructed labor. A hemostat is shown entering the urethral meatus. (Courtesy Mark Morgan, MD, Department of Obstetrics and Gynecology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

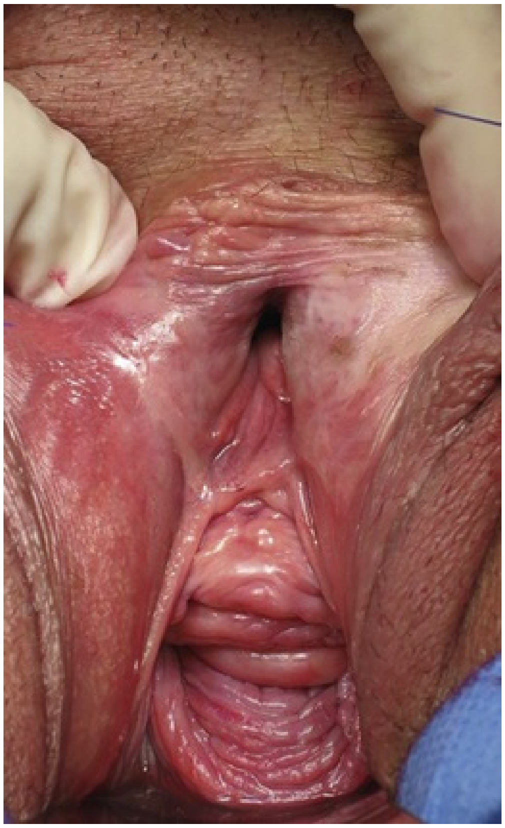

FIG. 129.31 Severe complete erosion of the urethra secondary to chronic indwelling urinary catheter. This patient with advanced multiple sclerosis underwent surgical bladder neck closure and ileovesicostomy (ileal chimney).

Symptoms of urethrovaginal fistulae are largely dependent on the size and location of the fistula along the urethral lumen. A small fistula may produce only minimal leakage, whereas a large urethrovaginal fistula can cause continuous urine drainage. **Proximal fistulae can be associated with stress incontinence, or, continuous incontinence neck similar to that associated with VVF if they are located at the bladder. Distal fistulae beyond the sphincteric mechanism may be completely asymptomatic or may be associated with a splayed urinary stream.** Occasionally, distal fistulae are associated with vaginal voiding and pseudo-incontinence, so called because the patient reports urinary incontinence that occurs only when rising from a seated position after voiding. This occurs as a result of urine accumulation in the vagina during voiding, with emptying occurring on standing—so-called vaginal voiding or vaginal reflux (Fig. 129.32).

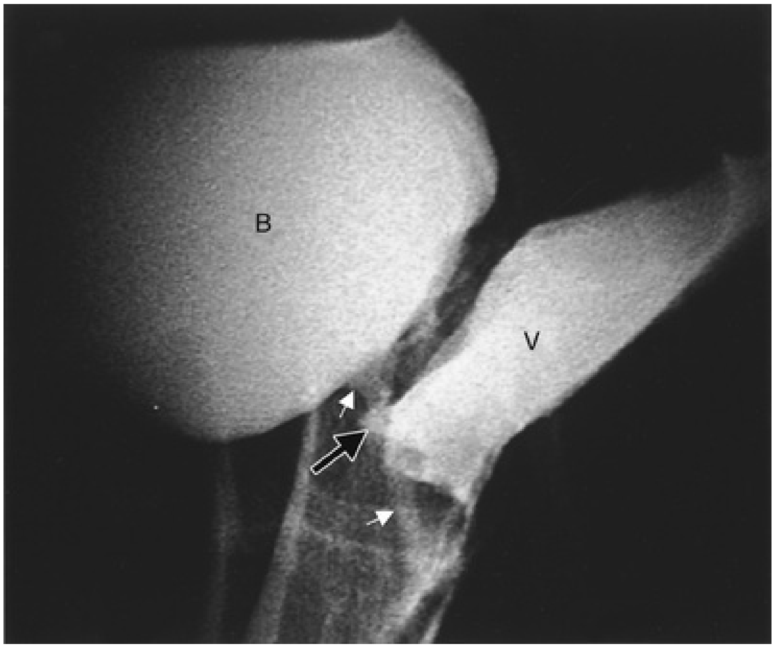

FIG. 129.32 Urethrovaginal fistula on lateral voiding image from voiding cystourethrography demonstrates fistula *(black arrow)* in this patient with a primary symptom of vaginal voiding. The urethra proximal and distal to the fistula is well opacified *(white arrows). B,* Bladder; *V,* vagina.

Diagnosis

The diagnosis of urethrovaginal fistula can often be made on physical examination and cystourethroscopy; however, voiding cystourethrography is extremely useful (Fig. 129.33), especially in complex cases. Double-balloon urethrography is the classic examination to show urethral diverticulum and urethrovaginal fistula, but 3D MRI or CT scan is being used more widely (Abet et al., 1983; Quiroz et al., 2010; Schoellnast et al., 2004). Ultrasound can be useful as well (Ying et al., 2010). Small fistulae may be very difficult to locate on physical examination, even with a speculum, because of the surrounding vaginal rugation (Fig. 129.34). An associated VVF will be found in up to 20% of cases, and therefore a thorough evaluation of the entire lower urinary tract is warranted (Lee et al., 1988).

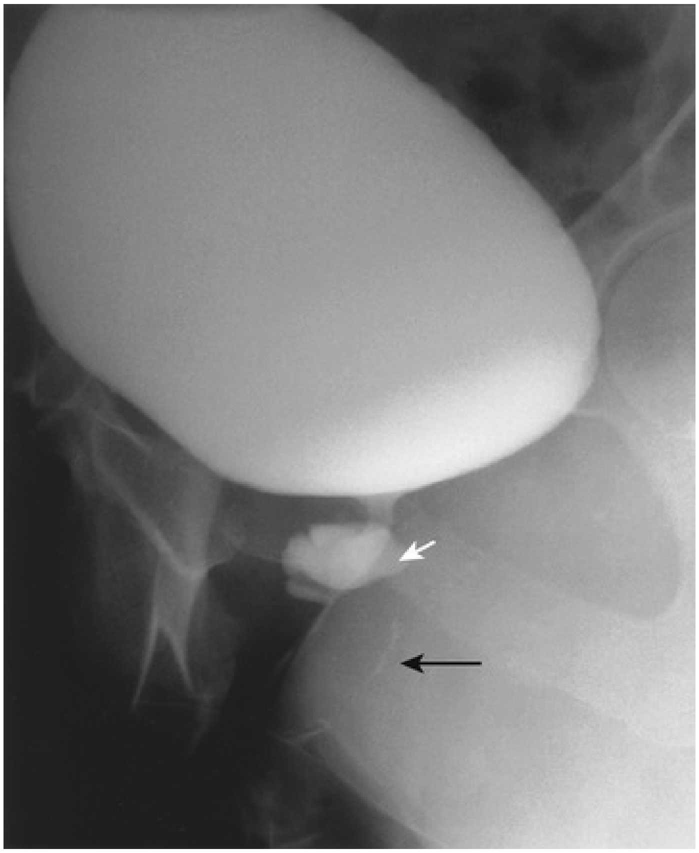

FIG. 129.33 This patient was referred for the evaluation of persistent incontinence after urethral diverticulectomy. A voiding cystourethrogram demonstrates incomplete resection of the urethral diverticulum *(white arrow)* with a pinpoint postoperative urethrovaginal fistula (*black arrow* shows a small amount of contrast material faintly outlining the anterior vaginal wall). Resection of the residual diverticulum with repair of the fistula by a Martius flap was curative.

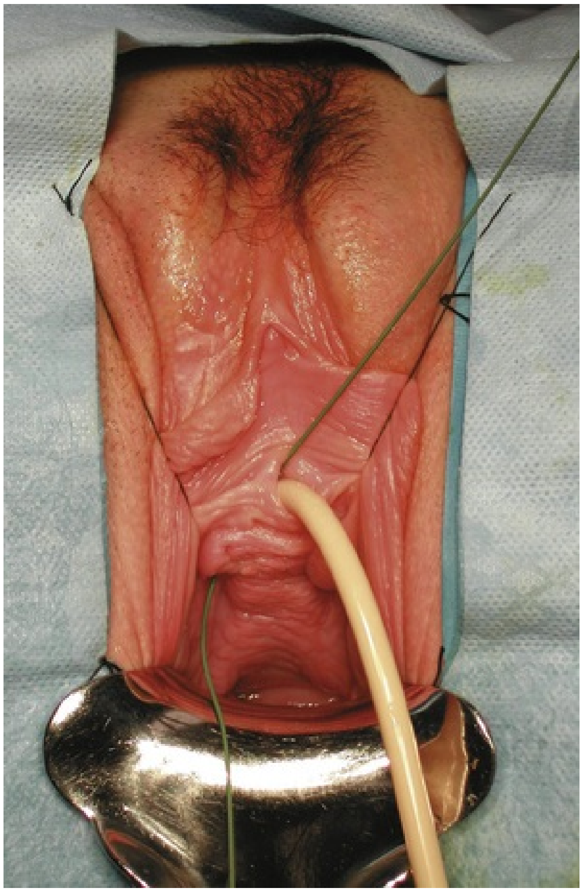

FIG. 129.34 Urethrovaginal fistula. Identification of the exact fistula tract can be difficult in redo cases. Passage of a flexible wire endoscopically from the urethral lumen into the vagina can aid in locating the fistula tract.

Endoscopic examination of the urethra should be performed. However, because of its short length, the female urethra may be difficult to fully examine with a standard rigid cystoscope, because the irrigation fluid is discharged 1 to 2 cm proximal to the lens. A flexible cystoscope or a specially designed female cystoscope with a short beak is very helpful in visualizing the entire urethral lumen, because the irrigation fluid is discharged next to the lens, distending the adjacent urethral lumen (Fig. 129.35). Once the diagnosis is made on cystoscopy, the bladder is examined for additional fistulae.

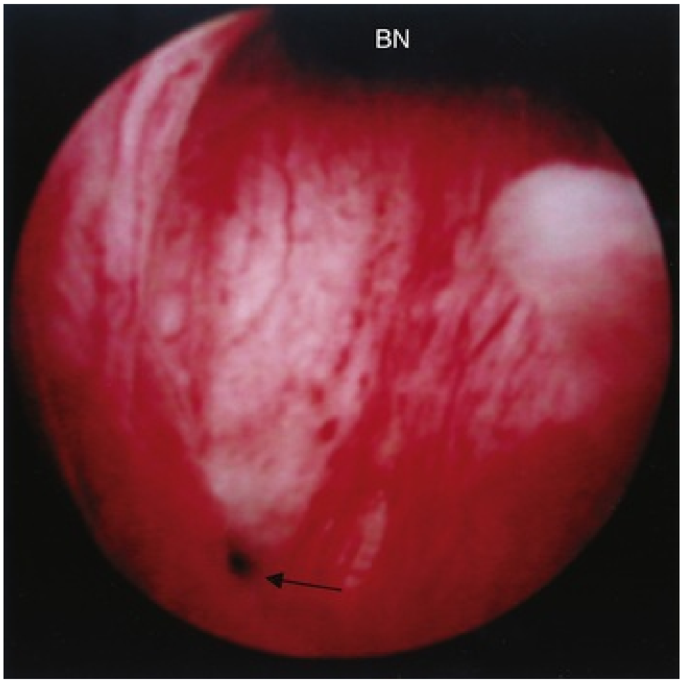

FIG. 129.35 Endoscopic view of a urethrovaginal fistula *(arrow).* This patient reported ongoing urinary incontinence for 10 years after an endoscopic bladder neck suspension. *BN,* Bladder neck.

Video-urodynamics may accurately characterize any associated incontinence, including that associated with detrusor dysfunction, although this will not often influence the decision to close the fistula. This study also allows assessment of the anatomic relationship of the fistula to the bladder neck and urethra, as well as examination for associated VVF.

Treatment of Urethrovaginal Fistulae

Several techniques for urethrovaginal fistula closure have been described. A vaginal approach is mostly used. Surgical correction intends to create a continent urethra that permits volitional, painless, and unobstructed passage of urine. Depending on the size, localization, and cause of the fistula and the amount of tissue loss, urethral reconstruction techniques may be necessary to restore the urethra and to achieve postoperative continence (Blaivas and Purohit, 2008).

Vaginal Approach

Goodwin and Scardino (1980) described in their series that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, but that an abdominal approach only leads to a successful closure in 58% of cases. A vaginal approach required less operating time and had less blood loss and a shorter hospitalization time.

Most authors describe surgical principles that are identical to those of vesicovaginal fistula repair: identifying the fistula, creation of a dissection plane between vaginal wall and urethra, watertight closure of urethral wall, eventual interposition of tissue, and closure of the vaginal wall. Primary closure rates of 53% to 95.4% have been described. Pushkar et al. (2006) described a series of 71 women, treated for urethrovaginal fistula; 90.1% of fistulae were closed at the first vaginal intervention. In addition, 7.4% were closed at a second vaginal intervention. Despite successful closure, stress incontinence developed in 52%. The stress incontinent patients were treated with synthetic or autologous slings, and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation or urethrotomy (Pushkar et al., 2006).

Advancement flaps of the vaginal wall can be used to cover the urethral suture line. In some cases more advanced methods are used to close or to protect the urethral closure.

In cases of difficult dissection and visualization, urethral sectioning has been advocated (Parks, 1965). This technique is also being used in the repair of complex urethral diverticula (Rovner and Wein, 2003). Fistulae that are located in the distal third of the urethra may also be marsupialized without compromising the continence mechanism (Lamensdorf et al., 1977). Distal urethrovaginal fistula may be entirely without symptoms, and in such cases, repair is not mandated.

Blaivas advocates that vaginal flaps are usually the best option in dealing with urethral reconstruction, next to the possibility of offering anterior or posterior bladder flaps. Options for vaginal repair of fistula include primary closure, peninsula flaps, bilateral labial pedicle flaps, and labial island flaps. Outcomes are optimized by using exacting surgical principles during repair and careful postoperative management by an experienced reconstructive surgeon (Blaivas and Purohit, 2008). Patients with urethrovaginal fistulae resulting from synthetic slings should be counselled that de novo or persisting stress incontinence can occur and that additional conservative or surgical treatment may be necessary (Blaivas and Mekel, 2014; Lee and Zimmern, 2016; Reisenauer, 2015).

Labial and Vaginal Flaps and Neourethra

The simplest flap is a vaginal advancement flap (Fall, 1995).

Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect but can also be used to create a tubular neo-urethra (Jiang et al., 2017; Pushkar, 2009; Xu et al., 2009). The construction of a neo-urethra has mostly been described in traumatic causes. In some cases a transpubic approach has been used (Huang et al., 2003). The numbers of patients reported are small, and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbocavernosus tissue can be incorporated in the pedicled flap and probably offers a better vascularization and more bulking to the repair. This could allow a safer placement of a sling afterward, in those cases in which bothersome stress incontinence would occur postoperatively (Candiani et al., 1993; McKinney, 1979).

Martius Flap.

Although in obstetric fistula repair it was not found to have any benefit in a large retrospective study in 440 women, the labial bulbocavernosus muscle/fat flap originally described by Martius is still considered by some to be an important adjunctive measure in the treatment of GU fistulae where additional bulking with well vascularized tissue is needed (Browning, 2006). Rangnekar et al. (2000) reported on 12 patients with urethrovaginal fistula of whom 8 were treated with a Martius flap and 4 with a conventional repair. Only 1 out of the 8 had a fistula recurrence, while 3 out of 4 of the conventional repairs broke down; however, these cases were not randomized between surgical techniques (Rangnekar et al., 2000). Punekar et al. (1999) described 15 patients with complex and recurrent fistula, using the skin island flap modification with excellent results. Radopoulos et al. (2008) published a small series of 5 recurrent and complex urethrovaginal fistulas that all healed using a Martius flap. The series of non-obstetric cause are small, and all of them are retrospective. There are no prospective data or randomized studies (Baskin et al., 2005; Birkhoff et al., 1977). The indications for Martius flap in the repair of all types of fistula remain unclear. In some cases the fistula repair can be combined with a Martius flap and an autologous sling with good results (Chodisetti et al., 2016).

Rectus Muscle Flap.

Rectus abdominis muscle flaps have been described by some authors (Atan et al., 2007; Bruce et al., 2000). Transvaginal urethrovaginal fistula closure was performed followed by a pedicled rectus abdominis muscle flap interposed between the fistula closure and vaginal suture line. The muscle flap was based on the inferior epigastric vessels and provided additional support to the urethra, bladder neck, and bladder base. Urethrovaginal fistula repair with the rectus abdominis muscle flap was successful in all cases without recurrence. Of the patients 5 (83%) were continent and able to void to completion at a mean follow-up of 23 months (range 2 to 66).

Other Interposition Material.

A range of nontraditional interposition flaps and grafts have been reported by several authors. All of the publications only report on small patient numbers without long-term outcomes or continence data.

Golomb et al. (2006) reported the use of a fascial patch, while adding a rectus fascia sling to a urethrovaginal fistula repair. Omentum is extensively used in abdominal approaches to VVF, but Janez et al. (1985) used it during a vaginal approach in three patients with good results.

The gracilis muscle can be used as well, although experience is limited. The graciloplasty was described by Ingelman-Sundberg in 1947 and has been adapted by other surgeons in the treatment of fistula. The number of patients reported is low as is the quality of the evidence (Hamlin and Nicholson, 1969; Ingelman-Sundberg, 1947; Patil et al., 1980).

Non-autologous material has been used as well. Lowman et al. (2007) described the use of porcine dermis interposition and a synthetic sling in an irradiated patient. Other biodegradable materials have been used, although the quality of available data is low and is insufficient to advocate their use (Lowman et al., 2007; Scott et al., 1991). Nonvascularized tissue grafts should be used with caution in such cases because the cause of the initial tissue damage resulting in fistula is often ischemic.

Posterior Approach

In cases of high fistula with difficult vaginal access, a perineal pararectal approach has been described. Some variations exist in the incisions and dissection planes. The anterior sagittal transrectal approach (ASTRA technique) and the posterior sagittal pararectal approach only have been reported in small observational series (Domini et al., 2000; Mauermann et al., 2004; Nikolaev and Bizhanova, 1998; Pena, 1989; Rossi et al., 1998).

Abdominal Approach

Female urethral injuries may cause serious morbidity with loss of the entire urethra in some cases. Ahmed et al. (2000) reported the results of construction of a neourethra by the flipped anterior bladder-tube technique in 5 girls aged 3 to 18 years (mean 8 years). All had pelvic fractures. Three patients came with a suprapubic cystostomy, 1 was totally incontinent, and another had an urethrovaginal fistula. Three had an associated vaginal injury. All 5 patients underwent construction of a neourethra using a flipped anterior bladder-wall tube (FABWT) and were followed for 18 to 80 months (mean 44 months). All patients were continent in the daytime, and 3 were voiding spontaneously without the need for catheterization. Two were managed by clean intermittent catheterization (CIC), one per urethram, and other via a continent abdominal stoma (Mitrofanoff) (Ahmed and Kardar, 2000).

A retropubic retrourethral technique has been described by Koraitim (1985). This approach allows a urethrovesical flap tube to be fashioned to form a continent neourethra. Urodynamic studies showed that the proximal vesical and distal urethral components of the neourethra contribute to sphincteric function. For larger fistula an enwrapping technique has been described as well (Massoudnia, 1974).

Complications

Little information can be found on complications after urethrovaginal fistula repair. A short report on 4 cases by Tehan et al. (1980) describes a disappointing experience in the transvaginal repair of these fistulae. These authors advocate a suprapubic bladder flap or bladder tube technique to achieve a functioning urethra. Complications after surgical repair have been fistula recurrence, urethral shortening and retraction, persistent reflux, bladder calculi, and bladder cancer (Tehan et al., 1980).

Follow-Up

In most series of urogenital fistula repair, follow-up is of very short duration. Dolan et al. (2008) investigated urinary and sexual symptoms and quality of life in a group of 31 women 50 months (median) after successful repair of urogenital fistula using the Bristol Female Lower Urinary Tract Symptom questionnaire. All women had undergone urodynamic investigation before their repair surgery, and only 36% had normal findings. Almost all women reported one or more symptoms, and for 65%, these caused at least “a bit of a problem,” although 87%

said that their urinary symptoms had little or no impact on their quality of life. Symptoms were similar in urethrovaginal and vesicovaginal fistulae and were not significantly associated with prior functional abnormality. Lee and Zimmern (2016) published 4- to 5-year results in 18 women with a 95% successful repair, although 33% of them had to be re-operated for minor complications.

Operative Technique

The repair of urethrovaginal fistulae is conceptually very similar to the vaginal flap repair of VVF described previously. The patient is positioned in the dorsal lithotomy position, and urethral and suprapubic catheters are placed. A ring retractor is helpful for exposure. Allis clamps are used to reflect the vaginal wall cephalad, exposing the fistula. In some patients an episiotomy may facilitate exposure of the fistula, improving visualization for repair (Webster et al., 1984). However, because of the distal (with respect to the vagina) location of these lesions, this is not usually necessary.

After infiltration of the fistula margins with injectable saline or local anesthetic with adrenaline, the fistula tract is circumscribed through the vaginal wall (Fig. 129.36). The fistula tract and immediate surrounding epithelium are not typically excised, because this will create a larger defect in the urethra that will be more difficult to close without undue tension. However, the vaginal wall is dissected several millimeters from the edge of the circumscribed fistula tract in a radial orientation. An inverted U- or J-shaped incision is marked along the anterior vaginal wall, with the base of the U or J at the margin of the circumscribed fistula tract. This is infiltrated with injectable saline, and the anterior vaginal wall flap is developed, exposing the underlying periurethral fascia to the level of the bladder neck or beyond, depending on the size and location of the fistula. If a concomitant anti-incontinence procedure is planned, dissection may be carried out laterally from the edges of the flap at the level of the bladder neck and the retropubic space entered.

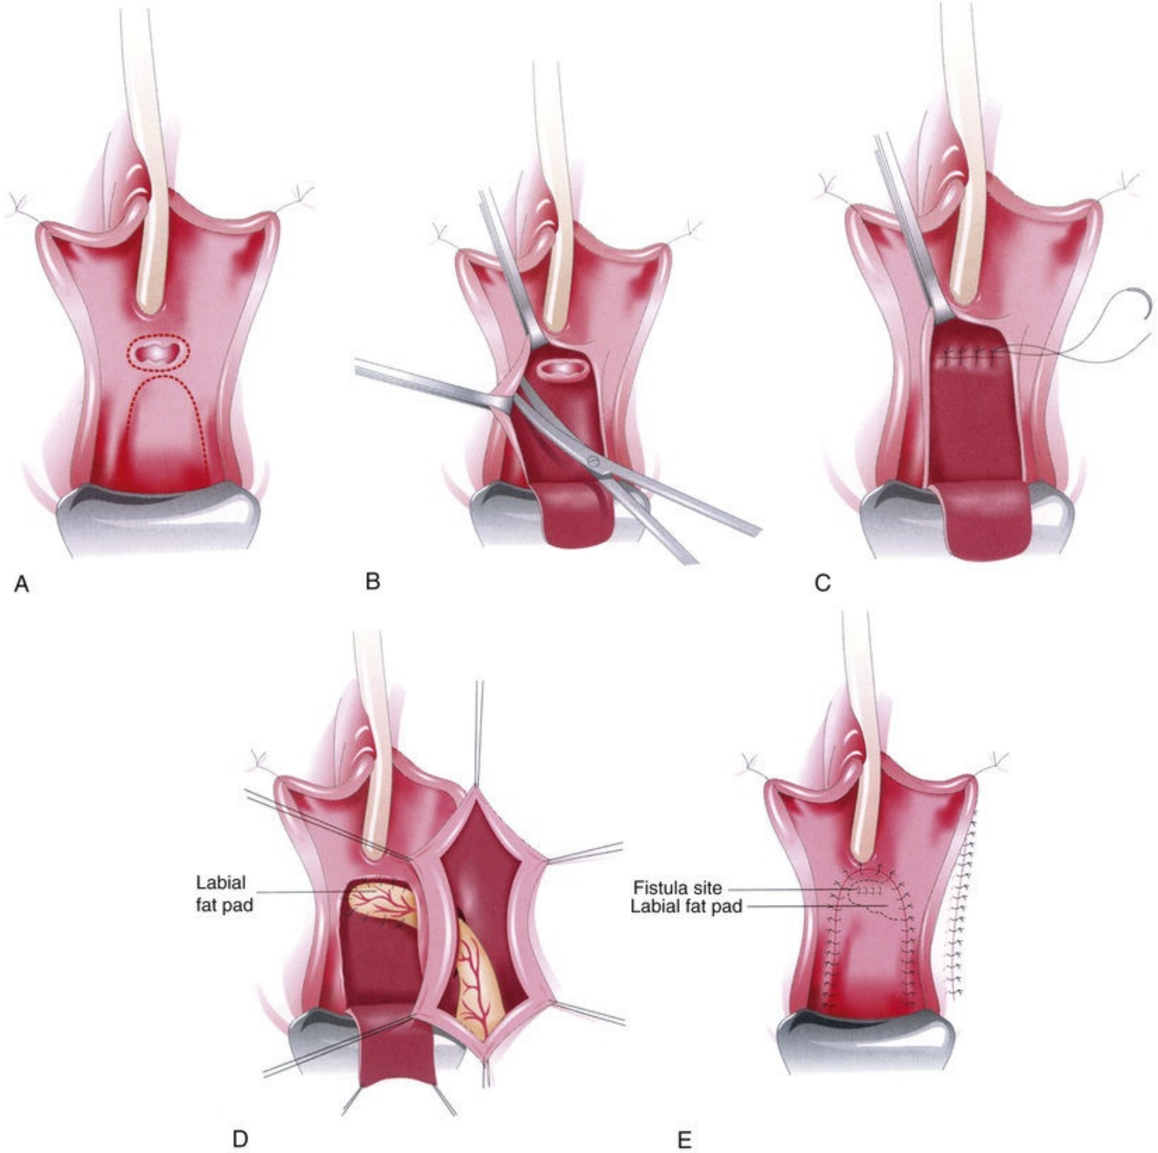

FIG. 129.36 Operative diagram of urethrovaginal fistula repair. (A) Inverted U incision is made in the anterior vaginal wall with the base of the U at the proximal margin of the fistula. The fistula is circumscribed. (B) The anterior vaginal wall flap is mobilized, exposing the periurethral fascia. Dissection is also carried out laterally and distally from the margins of the fistula. The edges of the fistula tract are not excised. (C) The epithelialized margins of the fistula tract are reapproximated with absorbable suture for the initial layer of closure. The periurethral fascia may be closed as a second layer, imbricating the initial layer of closure (not shown). (D) A Martius flap may be harvested from the labia majora and tunneled as an additional layer of closure. (E) The anterior vaginal wall flap is advanced over the closure and secured with absorbable suture. (From Leach GE, Kobashi KC: Urethral diverticulum and fistula. In: Cardozo L, Staskin D, editors. *Textbook of female urology and urogynecology*, London, 2001, Isis Medical Media, pp 721–745.)

The edges of the circumscribed tract are reflected over the fistula and apposed with absorbable suture to create the first layer of closure. The periurethral fascia is then reapproximated in a perpendicular suture to the first layer of closure, thereby minimizing overlap. At this point, a Martius flap or other adjuvant flap can be secured over the periurethral fascia. Finally, the anterior vaginal wall flap is brought over the repair, including a Martius flap if used, and secured beyond the original fistula tract.

Suprapubic as opposed to urethral catheterization postoperatively for at least 14 days to allow adequate healing has been suggested (Tehan et al., 1980), although the use of only a single drainage catheter postoperatively is not universally agreed on. Other authors use a suprapubic and a urethral catheter (Leach, 1991). Anticholinergics are administered liberally to reduce bladder irritability. Usually a VCUG with contrast administered through the suprapubic tube is obtained to document resolution of the fistula.

SUI may persist after repair of urethrovaginal fistulae. Whether repair of SUI should be done concomitantly with the fistula surgery or should be deferred until after repair of the fistula is controversial. Blaivas (1989) argued that sphincteric incontinence should be repaired at the time of fistula surgery, with a Martius flap interposed between the fistula repair and a pubovaginal fascial sling. Webster et al. (1984) suggested that SUI associated with a proximal or mid-urethral urethrovaginal fistula should not be corrected until the fistula is closed and the patient reassessed for persistent incontinence. These authors suggest, however, that SUI associated with distal urethrovaginal fistula can be repaired concomitantly.

Overall, the success rate of urethrovaginal fistula repair is variable but is not generally considered to be as high as that for VVF repair (Gerber and Schoenberg, 1993). Not uncommonly, two or more procedures may be necessary to achieve a satisfactory result (Webster et al., 1984).

Key Points: Urethrovaginal Fistulae

- Distal urethrovaginal fistulae are often asymptomatic, whereas proximal fistulae may cause intermittent or constant urinary leakage.
- Urethrovaginal fistulae caused by surgical trauma may be difficult to visualize on physical examination or cystoscopy.

- Diagnosis of a urethrovaginal fistula is best made with VCUG.
- Repair of urethrovaginal fistulae can be challenging and often involves an interpositional tissue flap because of the relative lack of surrounding connective tissue in the mid-urethra and distal urethra.

Uroenteric Fistulae

Etiology and Presentation

The most common non-obstetric causes of fistula involving the gastrointestinal tract are diverticular disease, Crohn disease, and malignant disease or its treatment (Chadha et al., 2008). **Less common causes include radiation, infection, and trauma (external penetrating trauma), as well as iatrogenic surgical trauma.** There are few data on the incidence of fistula formation in these conditions, although published estimates are in the range of 2% to 6% in Crohn disease (Ben-Ami et al., 2002; Greenstein et al., 1984; Margolin and Korelitz, 1989) and 20% in diverticular disease (Woods et al., 1988).

The peak incidence of vesicoenteric fistula occurs at 55 to 65 years of age, although fistulae from Crohn disease manifest much earlier (Badlani et al., 1980). Approximately 2% of patients with diverticulitis may experience a colovesical fistula as a complication of their disease (Hafner et al., 1962). In a multi-institutional retrospective review of 400 patients with Crohn disease over a 10-year period, 8 patients (2%) were found to have enterovesical fistulae, 7 had ileovesical, and 1 had colovesical fistulae (Gruner et al., 2002). The underlying GI tract disease strongly influences the type of fistula (Najjar et al., 2004); **ileovesical fistulae are more common in Crohn disease than in cancer, and colovesical fistulae are usually a result of diverticulitis.**

Intestinal fistulae in Crohn disease most typically involve the small bowel, although communication with urinary tract and large bowel are also found; involvement of the bladder was reported in 27% and of the colon in 14% in one series (Glass et al., 1985). Three large series examining the urologic complications in association with Crohn disease reported that although a majority of patients were female, the most serious complications were seen in males; most significantly, 30 of 31 or 93% of the ileovesical fistulae described in these series were in men (Ben-Ami et al., 2002; Kyle, 1980; Saint-Marc et al., 1995).

Although clearly diverticular disease involves the large bowel primarily in all cases, diverticular fistulae have been reported to communicate with the bladder in 65% of cases, the vagina or uterus in 28%, and small bowel in 7% (Woods et al., 1988). Diverticular disease is the most common cause of colovesical fistula in most reports, accounting for up to 75% of cases (Ferguson et al., 2008; Garcea et al., 2006; McBeath et al., 1994; Mileski et al., 1987; Najjar et al., 2004; Pokala et al., 2005; Pollard et al., 1987; Schofield, 1988), with colon cancer, bladder cancer, radiotherapy, and Crohn disease accounting for the remainder (Golabek et al., 2013).

Previous hysterectomy appears to be a significant factor in the incidence of fistula associated with diverticular disease (Bahadursingh and Longo, 2003). In a national case-controlled study from Sweden involving a total of 783,245 women over a 30-year period, the risk of undergoing fistula surgery increased 4-fold in hysterectomized women without diverticulitis, 7-fold in women with diverticulitis without hysterectomy, and 25-fold in hysterectomized women with diverticulitis (Altman et al., 2010; Table 129.3).

TABLE 129.3

Causes of Vesicoenteric Fistulae

Diverticulitis	65%–75%
Malignancy	10%–15%
Crohn disease	5%–6%
Other (trauma, appendiceal abscess, foreign body)	<5%

Data from Morse and Dretler, 1974; Amendola et al., 1984; Pollard et al., 1987; Schofield, 1988; Walker et al., 2002.

Symptoms of vesicoenteric fistulae may originate from the urinary or GI tract; however, in general, lower urinary tract symptoms are more common at presentation (Morse and Dretler, 1974). In the early stages, symptoms are nonspecific and relate to lower urinary tract dysfunction. Lower urinary tract symptoms include pneumaturia, frequency, urgency, suprapubic pain, recurrent urinary tract infections (UTIs), and hematuria (Table 129.4). **Pneumaturia is considered the most common presenting symptom noted in 50% to 70% of cases** (Morse and Dretler, 1974; Solem et al., 2002). GI symptoms may include fecaluria and tenesmus. **The classic presentation of vesicoenteric fistula is described as Gouverneur syndrome and consists of suprapubic pain, urinary frequency, dysuria, and tenesmus** (Chebli et al., 2014; Vidal Sans et al., 1986). Recurrent UTIs or cystitis refractory to antibiotic therapy may suggest a colovesical fistula (Rao et al., 1987). Although it is rare for enterovesical fistulae to have sepsis as the presenting sign (Woods et al., 1988), patients with sepsis are found to have urinary obstruction in approximately 70% of cases (Mileski et al., 1987).

TABLE 129.4

Presenting Symptoms of Vesicoenteric Fistulae

Pneumaturia	52%–77%
Fecaluria	36%–51%
Urinary tract infection symptoms (frequency, urgency, dysuria)	44%–45%
Fever and chills	41%
Abdominal pain	25%
Nonspecific gastrointestinal symptoms	25%
Hematuria	5%–22%
Orchitis	10%
Urine per rectum	5%

Data from Morse and Dretler, 1974; Pontari et al., 1992; Najjar et al., 2004.

Pyeloenteric Fistulae

Pyelointestinal fistulae represent an epithelialized connection between the renal pelvis or collecting system of the kidney and the GI tract. **Chronic inflammatory disease, such as xanthogranulomatous pyelonephritis or other infectious diseases involving the kidney or bowel, historically has been the most common cause of this condition** (Hui Wu et al., 2014; Majeed et al., 1997; Yildiz et al., 1993)**. However, iatrogenic surgical trauma, especially that related to percutaneous renal surgery and percutaneous nephrolithotomy (PCNL), has been associated with an increasing number of such fistulae** (Padovani et al., 2015; Un et al., 2015; Fig. 129.37). Penetrating external trauma, malignancy, ulcer disease, ingested foreign bodies, and complex calculous disease may also result in pyeloenteric fistulae (Atalla et al., 2009; Cooper et al., 1997, Hernandez et al., 2007; McDougal and Persky, 1972). **Right-sided pyeloenteric fistulae most often involve the duodenum because of their close anatomic relationship, whereas left-sided pyeloenteric fistulae most commonly involve the descending colon.**

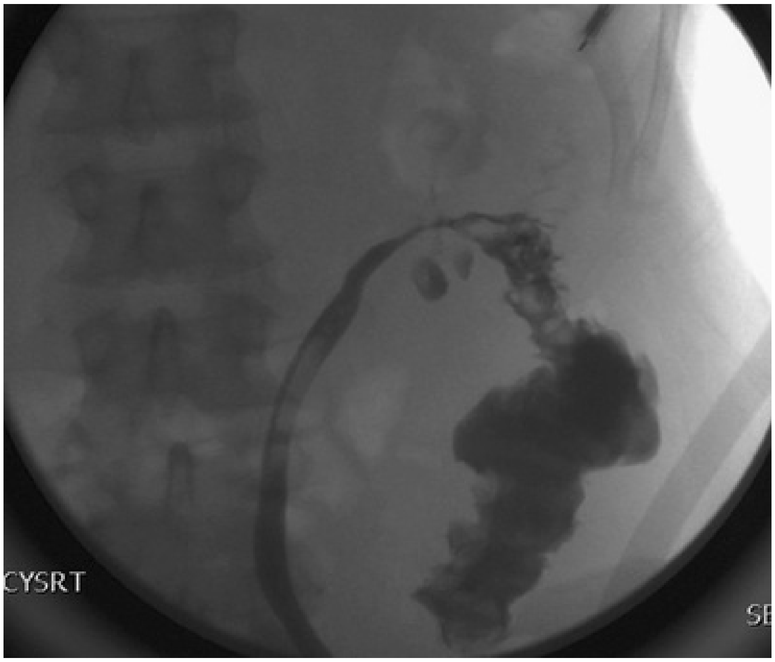

FIG. 129.37 Pyelocolonic fistula after cryosurgical ablation of a renal tumor. Retrograde pyeloureterogram demonstrates contrast extravasation into the colon.

Diagnosis

Many studies exist for the diagnosis of enterovesical fistulae; however, there are significant problems with false negatives and false positives among the diagnostic modalities, and thus the diagnosis is often made on clinical grounds. **Cystoscopy has the highest yield in identifying a potential lesion, with some type of abnormality noted on endoscopic examination in more than 90% of cases** (Morse and Dretler, 1974; Fig. 129.38). **However, the findings on cystoscopy are often nonspecific and include localized erythema, papillary, or bullous change; a definitive diagnosis using cystoscopy can be made in only 35% to 46% of cases** (Pontari et al., 1992; Woods et al., 1988). Cystoscopy and biopsy of abnormal-appearing tissue or an established fistula tract in the setting of a history of malignancy are indicated to evaluate for the possibility of a malignant fistula.

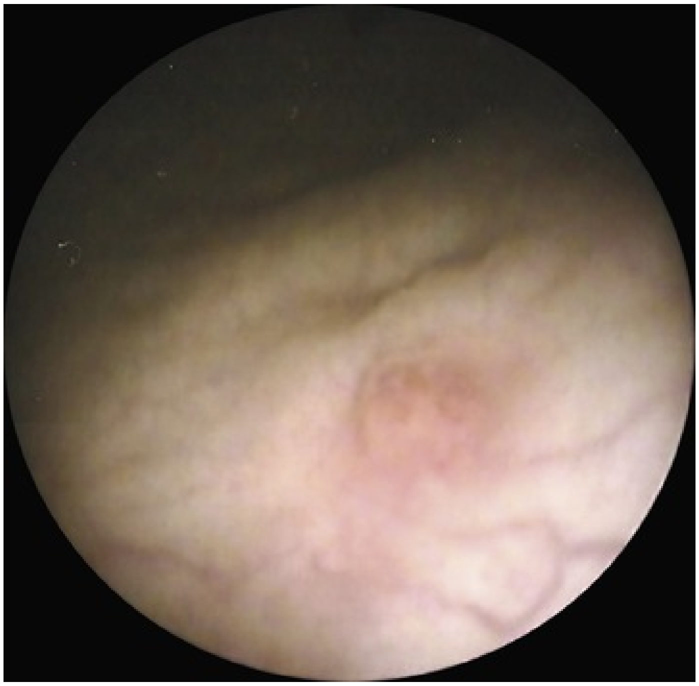

FIG. 129.38 Cystoscopic view of a chronic long-standing colovesical fistula. Unlike the majority of these fistulae, there is minimal inflammation around the fistula tract.

Cross-sectional imaging, especially CT scanning, has become the imaging modality of choice (Golabek et al., 2013). **The triad of findings on CT that**

are suspicious for colovesical fistulae consist of (1) bladder wall thickening adjacent to a loop of thickened colon, (2) air in the bladder (in the absence of previous lower urinary manipulation), and (3) the presence of colonic diverticula (Fig. 129.39). Ultrasonography has also been reported to be useful in the diagnosis of colovesical fistulae. A characteristic "beak" sign may be noted; however, this study is not usually performed in the routine evaluation of the patient with a suspected enterovesical fistula (Chen et al., 1990).

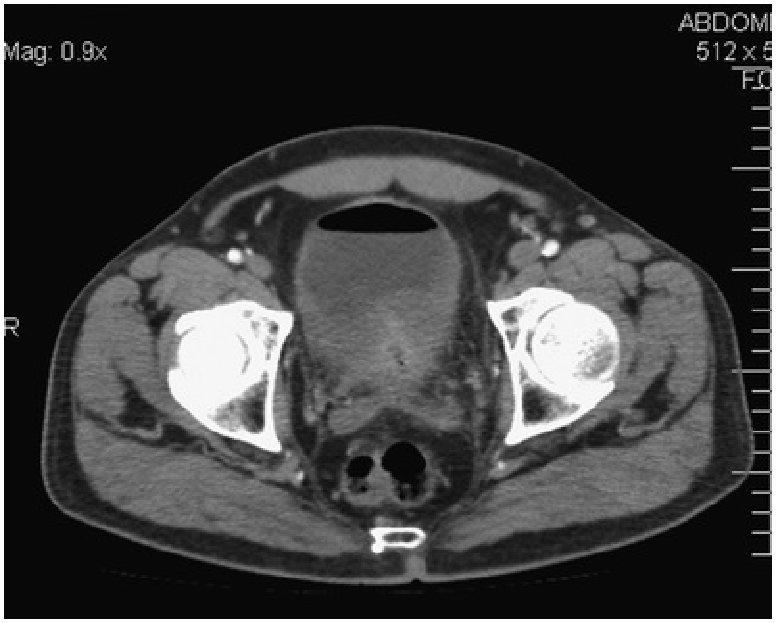

FIG. 129.39 Computed tomography scan of colovesical fistula. Note the air in the bladder with the thickened posterior bladder wall.

Cystography and transrectal contrast studies (e.g., barium enema) are in general less likely to demonstrate the fistula (Pindoria et al., 2014).

Management

Nonoperative management is a viable option in selected patients with vesicoenteric fistula. Solkar et al. (2005) and Radwan et al. (2013) reported on more than 80 patients that were diagnosed with CVF. Those managed conservatively were older and more frail. At 1 and 3 years after diagnosis there was no difference in mortality between these two groups (Radwan et al., 2013; Solkar et al., 2005). **In nontoxic, minimally symptomatic patients with nonmalignant causes of enterovesical fistulae, a trial of medical therapy**

including intravenous total parenteral nutrition, bowel rest, and antibiotics may be warranted. This may be the preferred initial approach, especially in patients with Crohn disease, in whom the notion of immediate exploratory laparotomy and bowel resection is often discouraged because of the chronic relapsing nature of the disease (Evans et al., 2003)**. There is also the potential for successful medical management of other fistulae resulting from inflammatory bowel disease** (Mahadevan et al., 2003). Ileovesical fistula in Crohn disease may be managed with antibiotics, nutritional support, often including total parenteral nutrition, and various combinations of immunomodulatory agents. In a nonsystematic review of the management of internal fistulae in Crohn disease, Levy and Tremaine (2002) described the drugs that have been reported to close internal fistulae partially or completely, including azathioprine, 6-mercaptopurine, mycophenolate mofetil, cyclosporine A, tacrolimus, and infliximab.

One case series of 500 patients with Crohn disease included 17 with enterovesical fistulae; all received sulfasalazine, most were treated with corticosteroids and antibiotics intermittently, and 8 in addition received 6-mercaptopurine. Although it is not clear that their fistulae closed completely, 6 continued on medical treatment alone for several years (Margolin and Korelitz, 1989).

Present et al. (1999) reported a placebo-controlled randomized trial of the tumor necrosis factor-α (TNF-α) neutralizing agent infliximab, a murine-human chimeric monoclonal antibody that binds the soluble subunit and the membrane-bound precursor of TNF-α, in patients with externally draining fistulae associated with Crohn disease. Adverse events were very common, but complete resolution of all fistulae was achieved in 55%, and 50% reduction in fistulous drainage was achieved in 68% of patients on 5-mg infliximab. This study did not include intestinovesical fistulae, although a case of successful use of infliximab in an ileovesical fistula has been reported (Game et al., 2003).

The goal of operative management is to separate and close the involved organs with minimal anatomic disruption and normal long-term function of both systems. Unfortunately, enterovesical fistulae may be complicated by intense pelvic inflammation, pelvic abscess, and phlegmon formation (in some cases), requiring complex staged reconstructions (Shackley et al., 2000). Bowel resection and/or partial cystectomy may be necessary to obtain viable tissue margins to ensure adequate, watertight closure of the involved viscera. An interpositional flap of greater omentum is often placed between the repaired bowel and urinary bladder to prevent overlapping suture lines and provide a well-vascularized surface for healing.

Single and multistage procedures have been advocated, depending on the clinical circumstances (Harris et al., 2017; Mileski et al., 1987; Morse and Dretler, 1974). A one-stage procedure involves removal of the fistula, closure of the involved organs, and primary reanastomosis of the bowel after resection of the involved bowel segment. A two-stage approach advocates removal of the fistula, closure of the involved organs, and creation of a temporary proximal diverting colostomy, with a later return to the operating room for colostomy takedown once the fistula tract has been demonstrated to be closed. **The choice of whether to proceed with a one-stage or two-stage repair is influenced by the location and cause of the fistula, the patient's general condition, the presence of a pelvic abscess, and the presence of colonic obstruction**. **Patients with an inflammatory cause of the fistula but without gross contamination can be treated with a one-stage procedure, whereas those with an unprepared bowel, gross contamination, or abscess may require a multistage procedure** (Mileski et al., 1987). As noted previously, most patients with colovesical fistulae present themselves electively with lower urinary tract symptoms, not emergently in extremis with sepsis. Therefore adequate preoperative support, eventually including bowel preparation, nutritional supplementation, and appropriate antibiotics, can be used in the majority of patients, allowing an elective one-stage approach.

The authors of many case series have advocated a one-stage approach in the majority of cases but have indicated that this should be limited to patients whose nutritional state is good and in whom there is no evidence of severe inflammation, radiation injury, advanced malignancy, intestinal obstruction, major medical problem, or advanced age. More recent series have tended to imply a greater advocacy of the one-stage approach; Garcea et al. (2006) in a series of 90 patients with colovesical fistula reported primary anastomosis in 61 of 65 (94%) cases wherein left colon resection was undertaken. Balaguera et al. (2006) argued against diverting colostomy or Hartmann procedure as being unnecessary and possibly resulting in additional morbidity.

In addition to the aforementioned criteria, it is intuitive that the more complex a fistula tract, the more relevant a phased approach to treatment becomes. Shackley et al. (2000) described a series of 10 patients with highly complex fistulae involving 3 to 6 separate organs and surfaces. They advocate a three-stage multidisciplinary management package, involving (1) an acute stage involving proximal defunctioning and distal drainage of the GI and urinary tracts to isolate the fistula, together with the eradication of sepsis; (2) a recovery stage consisting of total parenteral nutrition, organ support, radiologic planning of surgical reconstruction, and intensive nursing; (3) joint urologic and GI reconstructive surgery when the patient was stable and nutritionally replenished and the sepsis was controlled. The mean time to reconstruction was 5 (1 to 20) months; the fistulae were treated successfully in all patients, with functional restoration in 4 and/or diversion of the GI and urologic tracts in 6 (Shackley et al., 2000).

Laparoscopic management of colovesical fistulae has been reported, albeit with a relatively high rate of conversion to open repair (Badic et al., 2017; Marcucci et al., 2017). Several reports have described a laparoscopic approach to one-stage treatment of colovesical fistulae. The overall conversion rate was seen to be higher for fistulae involving the duodenum, vagina, and sigmoid colon than for those involving the bladder (10%), although a low threshold for conversion to open surgery was advocated in one series (Pokala et al., 2005).

Key Points: Vesicoenteric Fistulae

- The most common cause of vesicoenteric fistulae is diverticulitis.
- Presenting symptoms are usually urinary, most commonly pneumaturia.
- Diagnosis is generally made with a combination of cystoscopy and cross-sectional imaging, including a CT scan.
- Repair of colovesical fistulae involves a single-stage or multistage procedure, depending on a number of clinical factors, including the presence of gross fecal contamination and infection.

Rectourethral Fistulae

Acquired rectourethral fistula (RUF) may occur in the male under a variety of clinical circumstances, including those related to prostatectomy for benign or malignant disease (Harris et al., 2017)**, cryotherapy, pelvic radiotherapy, anorectal surgery, external penetrating trauma** (Bukowski et al., 1995; Kucera et al., 2017), **urethral instrumentation** (Thompson and Marx, 1990), **locally advanced prostatic or rectal malignancy, infection** (e.g., TB) (Okaneya et al., 1988), **ruptured prostatic abscess, or inflammatory disease (e.g., Crohn disease)**.

Etiology and Presentation

The incidence of RUF after radical retropubic, laparoscopic, or robotic prostatectomy (RRP) is low, but because of the frequency with which the operation is performed, it is the most common cause of RUF in most modern series (Buckley, 2011; Masuda et al., 2010; Wedmid et al., 2011; Yildirim et al., 2012**)**. **Rectal injury during radical prostatectomy occurs in less than 1% to 2% of patients** (Borland and Walsh, 1992; Guillonneau et al., 2003). In a Mayo RRP series, there were 27 documented rectal injuries in 2212 patients (McLaren et al., 1993). In this series, 26 of 27 injuries were recognized intraoperatively and repaired. Six patients underwent temporary colostomy, and 4 patients developed RUF. Guillonneau et al. (2003) reported a 1.3% incidence of rectal injury in 1000 consecutive patients undergoing laparoscopic radical prostatectomy. In a German series of 2447 radical prostatectomies, the incidence of RUF was 0.53%. The risk of rectourethral fistulas was 3.06-fold higher (P = 0.074) for perineal (7 of 675, 1.04%) than for retropubic prostatectomy (6 of 1772, 0.34%). In robotic radical prostatectomy the incidence of RUF was 0.17% (11 in 6650 cases) in a multicenter study by Wedmid et al. and 0.2% in a series of 4440 patients. Cases in which rectal injury was identified intraoperatively required fewer surgical repeat interventions but ultimately each group had acceptable long-term urinary and bowel function results (Kheterpal et al., 2011; Wedmid et al., 2011).

In the setting of radical prostatectomy, a prior history of pelvic radiation therapy, rectal surgery, or transurethral resection of the prostate (TURP) is associated with an increased risk of RUF (Thompson and Marx, 1990). RUF that occurs after radical prostatectomy is usually seen at the vesicourethral anastomosis and is often caused by an unrecognized rectal injury at the time of surgery. However, when a rectal injury is recognized and repaired intraoperatively, RUF is extremely uncommon. Borland and Walsh (1992) reported 10 rectal injuries in 1000 non-irradiated patients undergoing radical prostatectomy at Johns Hopkins Hospital; however, no patient developed an RUF. Nine of 10 patients had a two-layer closure performed with an omental interpositional flap at the time of injury. One patient underwent a temporary diverting colostomy; the rectal injury was diagnosed and repaired on postoperative day 2. Anal sphincter dilation was performed on all patients, and they received 7 to 14 days of postoperative antibiotics. Also in robotic series primary closure of RUF has been described with good outcome (Wedmid et al., 2011).

The reported incidence of RUF after cryosurgical ablation as primary therapy for localized carcinoma of the prostate is 0.5% to 5% (Hanna et al., 2014; Zippe, 1996). Partial gland cryotherapy yields less RUF than total gland cryotherapy (0 vs. 1.2%) (Tay et al., 2016, 2017). The **rate of RUF after cryotherapy as salvage therapy for prostate cancer is somewhat higher at approximately 3.3% to 9%** (Vora et al., 2016). **The incidence of RUF after brachytherapy for prostate cancer as reported by** Theodorescu et al. (2000) **is 0.4%.** RUFs have also been reported to follow high-intensity focused ultrasound (HIFU) treatment (Uchida et al., 2015), HIFU combined with external beam radiotherapy (6% incidence) (Gelet et al., 2004; Uchida et al., 2011), laparoscopic radical prostatectomy (Guillonneau et al., 2003), and transurethral thermotherapy for benign prostatic hyperplasia (BPH) (Norby and Frimodt-Moller, 2000). The incidence of RUF in Crohn disease is estimated to be approximately 0.3% (Fig. 129.40). Fistulae caused by Crohn disease are complex, and management should be individualized (Cools et al., 1996; Zwintscher et al., 2015).

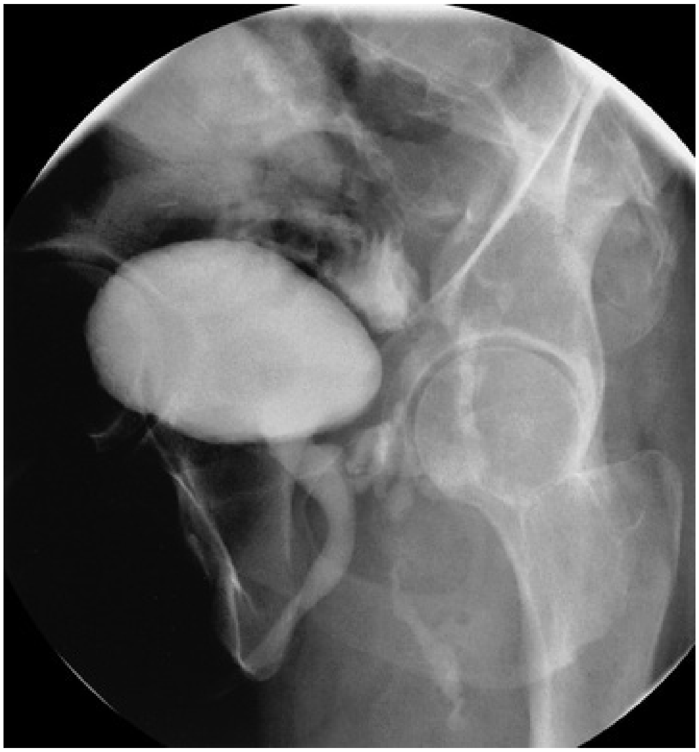

FIG. 129.40 Rectourethral fistula caused by Crohn disease. Contrast material is seen posterior to the bladder on this voiding image from voiding cystourethrography. (Courtesy Nancy Curry, MD, Department of Radiology, Medical University of South Carolina, Charleston, SC.)

The presentation of RUF is variable. **Symptoms may include fecaluria, hematuria, UTI, nausea, vomiting, and fever.** Peritonitis and sepsis may occur as well. Digital rectal examination often permits palpation of the fistula tract along the anterior rectal wall. **Cystoscopy and sigmoidoscopy visualize the fistula tract in the majority of cases and provide a mechanism for biopsy. In patients with a history of pelvic malignancy, biopsy of the fistula is suggested to evaluate for a local recurrence of the tumor** (Shin et al., 2000). A VCUG or retrograde urethrogram (RUG) usually provides a definitive diagnosis of RUF (Fig. 129.41). The exact anatomic location and size of the fistula are also usually well delineated on the VCUG or RUG, providing important information in surgical planning. Lateral projections may be necessary to visualize small fistulae, because contrast in the rectum or urethra can sometimes obscure extremely thin fistulous tracts (Karsten et al., 2016). Also PET/CT and MRI have a place in the imaging of RUF (Nguyen and Collins, 2011). **Upper tract imaging should be performed in patients with RUF to exclude a related ureteral injury. It is important to make an assessment of continence and sphincteric function in patients with RUF after radical**

prostatectomy. Given the location of most RUFs at or near the vesicourethral anastomosis and the membranous urethra, there is a risk for persistent severe stress incontinence postoperatively after RUF repair (Harris et al., 2017; Keller et al., 2015). In many patients with RUF and severe stress incontinence, closure of the RUF may not be sufficient to bring about continence. Additional procedures may be needed to bring about a satisfactory result in these patients; this is an important issue to discuss in preoperative patient counseling. Artificial sphincters are a feasible option after RUF repair (Selph et al., 2015).

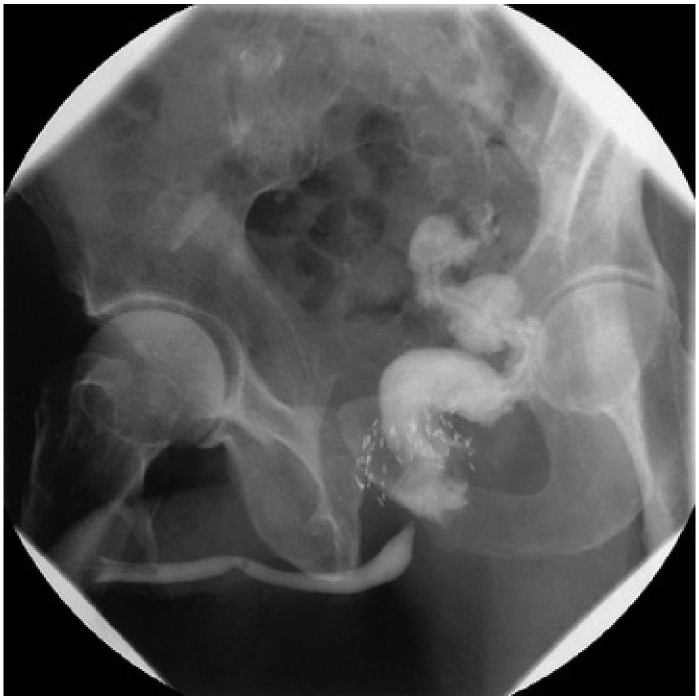

FIG. 129.41 Rectourethral fistula after brachytherapy for carcinoma of the prostate. A retrograde urethrogram demonstrates filling of the rectum in this patient who was seen several years after brachytherapy with fecaluria. The bladder is not opacified. The brachytherapy seeds can be seen in the area of the prostate.

A large patient cohort was published by Harris et al. (2017). After prostate cancer treatment 201 patients underwent rectourethral fistula repair. The fistula developed in 97 men (48.2%) after radical prostatectomy alone and in 104 (51.8%) who received a form of energy ablation. In the ablation group 84% of patients underwent bowel diversion before rectourethral fistula repair compared with 65% in the prostatectomy group. An interposition flap or graft was placed in 91% and 92% of the 2 groups, respectively. Concomitant bladder neck contracture or urethral stricture developed in 26% of patients in the ablation group and in 14% in the prostatectomy group. Postoperatively the rates of urinary incontinence and complications were higher in the energy ablation group at 35% and 25% versus 16% and 11%, respectively. The ultimate success rate of fistula repair in the energy ablation and radical prostatectomy groups was 87% and 99% with 92% overall success (Harris et al., 2017).

Thirty males (mean age 63 years) were reviewed. Prostate cancer treatment was the most common fistula cause (97%). Urinary drainage consisted of urethral catheter in all patients and suprapubic catheter in 14 (47%). The rate of fecal diversion was 67%. During a mean follow-up of 72 months, healing rate was 90% and recurrence rate 0. Spontaneous healing was achieved in 14 patients (47%): 8 (27%) without fecal diversion and 6 (20%) after fecal diversion. Thirteen patients (43%) required definitive intervention. The majority of operated patients underwent transanal or transperineal flap (endorectal, dartos, or gracilis) successfully. Only 2 patients (7%) required an abdominal approach (positive oncologic margins or nonfunctioning bladder). Fifteen out of the 20 patients (75%) who underwent fecal diversion had stoma closure with an overall permanent stoma rate of 17%. Long-term urinary incontinence was noted in 11 patients (37%). Six patients (20%) required permanent urinary diversion or drainage catheters. Algorithm-based treatment approach for rectourethral fistula is useful in the management of this rare condition. Selective fecal diversion is possible, and majority of patients who require definitive intervention can be treated with a transanal or transperineal approach. The rate of permanent stoma is low, but long-term urinary dysfunction is frequent (Keller et al., 2015).

Management

Most RUFs require surgical repair (Hanna et al., 2014; Harris et al., 2017), although it is clear that some close with conservative management. **RUF that follows open or laparoscopic prostatectomy may heal spontaneously with catheter drainage, bowel rest, and intravenous hyperalimentation. In some cases, fecal diversion is necessary.** Rassweiler et al. (2003) reported that 6 of 8 RUF patients were treated successfully in such a manner. Two patients required a temporary colostomy. Masuda (2010) and Thomas et al. (2010) reported spontaneous closure with the use of a protective temporary colostomy.

Harris et al. (2017) reviewed 201 patients from 4 high-volume centers. The fistula developed in 97 men (48.2%) after radical prostatectomy alone and in 104 (51.8%) who received a form of energy ablation. In the ablation group 84% of patients underwent bowel diversion before rectourethral fistula repair compared with 65% in the prostatectomy group. An interposition flap or graft was placed in 91% and 92% of the 2 groups, respectively. Concomitant bladder neck contracture or urethral stricture developed in 26% of patients in the ablation group and in 14% in the prostatectomy group. Postoperatively the rates of urinary incontinence and complications were higher in the energy ablation group at 35% and 25% versus 16% and 11%, respectively. The ultimate success rate of fistula repair in the energy ablation and radical prostatectomy groups was 87% and 99% with 92% overall success (Harris et al., 2017).

An algorithm-based approach has been advocated by Keller et al (2015). Thirty males (mean age 63 years) were reviewed. Prostate cancer treatment was the most common fistula cause (97%). Urinary drainage consisted of urethral catheter in all patients and suprapubic catheter in 14 (47%). The rate of fecal diversion was 67%. During a mean follow-up of 72 months, healing rate was 90% and recurrence rate 0. Spontaneous healing was achieved in 14 patients (47%): 8 (27%) without fecal diversion, and 6 (20%) after fecal diversion. Thirteen patients (43%) required definitive intervention. The majority of operated patients underwent transanal or transperineal flap (endorectal, dartos, or gracilis) successfully. Only 2 patients (7%) required an abdominal approach (positive oncologic margins or nonfunctioning bladder). Fifteen out of the 20 patients (75%) who underwent fecal diversion had stoma closure with an overall permanent stoma rate of 17%. Long-term urinary incontinence was noted in 11 patients (37%). Six patients (20%) required permanent urinary diversion or drainage catheters.

Surgical repair of RUF can be challenging, and the basic tenets of operative fistula repair are especially relevant in these cases (see Box 129.2). Several surgical approaches have been advocated and are outlined later. **Single and staged repairs have been described for the repair of RUF.** The controversy surrounding the staged repair centers on the issue of whether to perform fecal diversion at all, or whether to perform it before or at the time of repair of the urinary tract. Some authors have advocated fecal diversion and staged repair of all RUFs (Shin et al., 2000). This is considered the standard conservative approach and, in combination with an indwelling urethral catheter, permits a trial of spontaneous healing of the fistula without open manipulation of the urinary tract. In support of the single-stage repair, a successful one-stage approach limits the potential morbidity and cost of multiple procedures that, by design, accompany the staged repair. **Suggested guidelines for cases in which a one-stage approach may be appropriate include surgically induced, small RUFs not associated with infection or abscess** (Harris et al., 2017; Thomas et al., 2010). **Staged repairs may be considered in cases of large fistulae, those associated with radiation therapy, uncontrolled local or systemic infection, immunocompromised states, or inadequate bowel preparation at the time of definitive repair.**

Transrectal approaches with and without division of the anal sphincter have been described for the operative repair of RUF. A recent systematic review by Hechenbleikner et al. (2013) identified 416 patients, including 169 (40%) who had previous pelvic irradiation and/or ablation. Most patients (90%) underwent 1 of 4 categories of repair: transanal (5.9%), transabdominal (12.5%), transsphincteric (15.7%), and transperineal (65.9%). Tissue interposition flaps, predominantly gracilis muscle, were used in 72% of repairs. The fistula was successfully closed in 87.5%. Overall permanent fecal and/or urinary diversion rates were 10.6% and 8.3%, respectively. Most high-volume centers (≥25 patients) performed transperineal repairs with tissue flaps in 100% of cases. Regardless of complexity, rectourethral fistulas have an initial closure rate approaching 90% when the transperineal approach is used. Permanent fecal and/or urinary diversion should be a last resort in patients with devastated, nonfunctional fecal and urinary systems.

The York-Mason procedure is a transrectal, transsphincteric approach that has been found to be effective and to have low morbidity. Classically, this is a staged repair with fecal diversion performed before repair of the RUF. However, in patients with small, nonirradiated fistulae, a single-stage approach can be used, provided that a vigorous bowel preparation and broad-spectrum antibiotics are used (Renschler and Middleton, 2003). For repair of the urinary tract, the patient is placed prone on the operating room table in the jackknife position. A full-thickness incision through the posterior anus and dorsal rectal wall is performed and deepened down to the level of the coccyx through the external anal sphincter. Care is taken to mark or tag each layer of the anal sphincter as it is divided. Later in the procedure during closure, careful anatomic reapproximation of the layers of the external anal sphincter is necessary to avoid the devastating complication of anal incontinence postoperatively. The anorectal incision as described provides excellent exposure of the fistula in the anterior rectal wall. The fistula tract is excised, and the anterior rectal wall is mobilized circumferentially around the fistula margins. The urethra is closed, and then the anterior rectal wall is closed. Finally, the rectal mucosa is reapproximated, providing a three-layer closure. Alternatively, after excision of the RUF, an anterior rectal wall flap can be developed and advanced over the fistula (al-Ali et al., 1997), similar to the transvaginal repair of VVF using the vaginal wall (see the previous discussion under VVF repair). Closure of the incision is performed by reapproximating the posterior rectal wall and then sequentially closing the layers of the anal sphincter in an anatomic fashion. Results with the York-Mason procedure have been excellent. In the largest series of patients undergoing the York-Mason procedure, Renschler and Middleton (2003) reported a successful repair in 22 of 24 patients. One of the two failures was subsequently repaired with another York-Mason procedure. No serious complications were reported, and no patient developed anal incontinence or anal stenosis. Similar excellent results have been noted by other authors (Forest et al., 2014; Hechenbleikner et al., 2013).

In contrast to the transrectal, transsphincteric approach, the **transanal approach** to RUF repair does not involve division of the anal sphincter. Exposure of the fistula is provided by dilation of the anus and fixed retraction. The Latzko procedure is one such approach (Hata et al., 2002). Similar to the Latzko method described previously for transvaginal VVF repair (see prior discussion), the fistula tract and surrounding rectal mucosa are denuded in all four quadrants. The fistula is then closed in three layers. The major disadvantage to this approach is the relatively poor exposure and lack of maneuverability within the operative field.

A **perineal approach** to RUF has been advocated by some authors in selected cases of RUF (Harris et al., 2017; Nyam and Pemberton, 1999; Zmora et al., 2003). Anatomically, this is a familiar approach for many urologists and has the added advantage of local access to a variety of potential interpositional flaps. Excellent results have been obtained with the perineal approach in combination with an interpositional flap, including gracilis muscle (Choi et al., 2014; Zmora et al., 2006) and pedicled Dartos muscle (Youssef et al., 1999). Transabdominal approaches to RUF have been described with limited success (Bukowski et al., 1995; Shin et al., 2000). The principal advantage of this technique is the availability of greater omentum for an interpositional flap. Potential disadvantages include the morbidity and prolonged postoperative convalescence associated with a laparotomy incision, poor exposure of the operative field (with limited maneuverability in the deep pelvis), and the risk of urinary and fecal incontinence.

The repair of RUF after external beam radiotherapy, **combined radiotherapy**, **brachytherapy, or cryosurgical ablation of the prostate can be especially difficult.** These fistulae may be large and are associated with considerable induration, fibrosis, and ischemia for a variable distance around the fistula, limiting reconstructive options. Repair of rectourethral fistulas caused by radiation has a significantly higher wound infection rate and median time to healing, and lower overall stomal reversal rate than nonradiation-induced rectourethral fistulas. Patients who had irradiated rectourethral fistulas required significantly more complex operations, likely contributing to the higher morbidity, mortality, and lower fistula closure rate (Hanna et al., 2014). In another group of 45 patients, those with prior radiation/ablation were significantly more likely to require permanent colostomy (25 of 29 [86%] vs. 0, $P < 0.0001$) and permanent urinary diversion as part of fistula management (27 of 29 [93%] vs. 1 of 16 [6%], $P < 0.0001$) (Linder et al., 2013). Similar findings were published by Beddy et al. (2013). Urinary reconstruction may not be possible in some of these cases, necessitating urinary diversion (Faris et al., 2014).

Key Points: Rectourethral Fistulae

- Rectourethral fistula is an uncommon outcome that results most commonly from the surgical treatment of localized prostate cancer.
- Diagnosis of RUF can be confirmed with VCUG.
- Treatment of RUF most commonly involves surgical repair; however, select patients may respond to conservative therapy, including Foley catheter drainage.

Urovascular Fistulae

Ureteroarterial fistulae are uncommon but can be life threatening because of massive bleeding in the ureter. They have a high mortality rate (Melegari et al., 2016). Predisposing factors are radiation therapy, vascular pathology, and ureteral stenting. Das et al. (2016) reviewed the literature and found 61 cases. In terms of treatment, endovascular stenting has emerged as an appealing initial modality and should be considered in stable patients with less favorable candidacy for open surgical intervention secondary to pre-existing comorbidities (Das et al., 2016).

Fistulae between the urinary tract and the vascular system are rare but have increased in frequency with the rapid integration of minimally invasive interventions in the upper urinary tract. These fistulae include communications between the upper urinary tract, including the collecting system or ureter, and an artery or vein.

Renovascular and Pyelovascular Fistulae

The most common causes of renovascular or pyelovascular fistulae are procedures in which percutaneous renal access is required, such as PCNL (Kyriazis et al., 2015**)**. Typically, these fistulae are created through puncture of an intrarenal vascular structure during creation or dilation of the nephrostomy tract. The damaged vessel may bleed on puncture or may not hemorrhage immediately because of external compression and tamponade from the catheter in the nephrostomy tract. However, on removal of the catheter, brisk bleeding may be noted into the relatively lower-pressure renal collecting system (Patterson et al., 1985). Alternatively, a long-term indwelling nephrostomy tube may lead to pyelovascular fistula formation. In this setting, a chronic indwelling large-bore nephrostomy tube may result in erosion into an adjacent renal vessel with resulting hemorrhage on removal of the tube. Lee et al. (1987) reported an 11.2% incidence of bleeding requiring transfusion and 1.2% incidence of bleeding requiring surgical or angiographic intervention after PCNL in 582 patients. Patterson et al. (1985) reported a vascular injury in 0.9% of 1032 patients undergoing percutaneous renal stone surgery. Other causes of renovascular fistula include external penetrating and blunt trauma (Stower et al., 1989), infection, and open renal surgery, including partial nephrectomy. Previous renal surgery is a risk factor (Yesil et al., 2013).

Patients with renovascular fistulae may have life-threatening hemorrhage and hypovolemic shock, or intermittent gross hematuria. After PCNL these fistulae may appear on removal of the nephrostomy tube with brisk bleeding out of the flank from the nephrostomy tube tract in combination with brisk hematuria, or they may manifest several days to weeks later with only hematuria (Clayman et al., 1984). CT scan is mostly used to make the diagnosis (Ganpule et al., 2013).

Treatment of renovascular fistulae is contingent on the presentation, cause, and hemodynamic stability of the patient. Patients with severe hemorrhage on removal of the nephrostomy tube can be temporized in some instances by replacing the tube, or, in large mature tracts, by placing a Foley catheter to tamponade the bleeding. In patients with ongoing bleeding, transcatheter angiographic embolization of the lacerated vessel is recommended. Even repeat arteriographic treatment can be necessary in case of persistent bleeding, which can be caused by missed pseudoaneurysm and the recanalization of the embolized vessels or new renal vascular lesion. The cause of these new renal vascular lesions is unknown. The lesion may be missed during the initial arteriography because of arterial spasm. Progressive deterioration of the injured vessel integrity could be the other possibility (Zhaohui et al., 2016).

Occasionally, flank exploration is necessary with partial or simple nephrectomy to control hemorrhage.

Ureterovascular Fistulae

Rarely reported before the advent of indwelling ureteral stents, ureterovascular fistulae are becoming increasingly common. **Most reported ureterovascular fistulae are ureteroiliac artery fistulae, although ureteroiliac vein fistulae have been reported as well** (Teuton et al., 1987). Ureteroaortic fistulae (and perigraft fistulae) are rare and have a high mortality (Deem et al., 2007; Nomoto et al., 2009; Ota et al., 2005). Usually endovascular treatment is used. Also aorto-ileal conduit fistula have been described (Ishibashi et al., 2007).

Most cases of ureteroarterial fistulae are reported in patients with a prior history of vascular disease, radiation therapy, and/or pelvic surgery, especially in the setting of indwelling ureteral stents (Aslam et al., 2010; McCullough et al., 2012).

A multidisciplinary approach is highly preferable for treating potentially life-threatening UIAF. Endovascular treatment with stent grafts is currently recommended in selected patients whenever possible, but open surgical treatment is required in certain patients with enteric contamination, abscess, local sepsis, or previously failed endovascular treatment (Hong et al., 2016).

Ureteral arterial fistula (UAF) is an uncommon condition characterized by a direct fistulous communication between a ureter and an iliac artery resulting in bleeding into the ureter, which can be massive and life threatening because of hemodynamic instability, as confirmed by the high mortality rate (7%–23% overall). This condition is actually increasing in frequency because of its relation to predisposing factors such as vascular pathology, previous radiation therapy, previous surgery, and necessity of ureteral stenting. Diagnosis is often challenging, as in most patients, the only symptom is hematuria and the treatment may require a multidisciplinary approach, including the expertise of the urologist, vascular surgeon, and interventional radiologist. Endovascular approach offers advantages over open surgery, decreasing morbidity (reduced risk of injury to adjacent structure) and shortening hospital stays. There is no consensus regarding the safety of intentional occlusion of the hypogastric artery: proximal occlusion of a hypogastric artery typically produces little or no clinical symptoms because of well-collateralized pelvic arterial networks. On the contrary, significant complications, such as colonic ischemia, spinal cord paralysis, buttock claudication, or erectile dysfunction, are well-recognized adverse events after hypogastric artery embolization, especially in bilateral cases. We describe our experience of a bilateral UAF treated with bilateral endovascular approach (Melegari et al., 2016).

Ureterovascular fistulae may manifest with microscopic hematuria, intermittent gross hematuria, or life-threatening exsanguinating hemorrhage. The key to the diagnosis of ureteroarterial fistulae is a high index of suspicion in an at-risk patient with gross hematuria (Batter et al., 1996)**. Intermittent gross hematuria or the sudden onset of massive hematuria in a patient with an indwelling stent and a history of previous iliac artery surgery or radiation should raise the suspicion of a ureteroarterial fistula**.

The routine urologic and radiologic evaluation of hematuria will not generally provide evidence of ureterovascular fistula (Quillin et al., 1994). This is especially true in patients with intermittent hematuria in whom there is no active bleeding at the time of the radiographic investigation, presumably because of thrombus over the site of the fistula. Selective or subselective arteriography of the iliac vessels may be more revealing in suspected cases, and provocative maneuvers, such as stent removal, or mechanical friction of the ureteral lumen by manipulation of the stent may be necessary to demonstrate the fistulous connection in patients without active bleeding who are undergoing angiography. **However, these adjuvant maneuvers should be performed only with extreme caution in an appropriate setting where immediate angiographic or surgical intervention is possible.** In the review by Batter et al. (1996), retrograde pyelography was diagnostic for only 6 of 10 patients in whom it was performed, and arteriography was diagnostic for a ureterovascular fistula in only 4 of 14 cases. Indirect evidence of a ureteroarterial fistula can be found on CT, but findings are usually nonspecific and only suspicious in retrospect after a confirmed diagnosis achieved by other means (Baum et al., 1987; Bergqvist et al., 2001). **Nevertheless, in a stable patient with a suspected ureterovascular fistula, a full radiographic evaluation may be pursued not only for diagnostic purposes but also to evaluate potential reconstructive options** (Batter et al., 1996) **and, in select cases, to perform therapeutic angiographic embolization procedures.**

Because these patients may be in extremis with hypotension and severe hemorrhage, surgical intervention must be considered early, especially because radiographic evaluation may be nondiagnostic. **In cases in which angiography is pursued for diagnosis, an endovascular stent graft may be placed** (Aarvold et al., 2008; Araki et al., 2008; Atmaca et al., 2013; Bergqvist et al., 2001; Brizuela et al., 2013; Copelan et al., 2014; Das et al., 2016; Sherif et al., 2002).

The management of these fistulae must be multidisciplinary. Endovascular stenting is the preferred initial treatment, but open surgical interventions with urologic and vascular reconstructions may be necessary (Das et al., 2016). A systematic literature review found reports of 139 cases of ureteroarterial fistula published from 1899 to 2008 (van den Bergh et al., 2009). All patients had hematuria; 25% also had other urinary symptoms or back pain. Almost all patients had a relevant past surgical history, particularly pelvic cancer surgery (54%) and arterial surgery with graft insertion (31%), and 61% had a ureteric stent in situ. The majority affected the iliac segment, and preoperative imaging was not always diagnostic. A total of 18 (13%) patients died as a result of the fistula. Many vascular and urologic interventions were used either alone or in combination. Later cases suggested that endovascular repair of the arterial defect gave the best results with lower mortality. Another, more recent, case series of 20 patients also showed a high mortality of 10% to 20% but did not find any difference in outcome between open or endovascular graft insertion techniques (Fox et al., 2011).

Key Points: Urovascular Fistulae

- Pyelovascular fistulae most commonly result from percutaneous interventional procedures to the upper urinary tract.
- Patients with suspected ureteroarterial fistulae usually have one or more risk factors including a history of pelvic radiotherapy, indwelling ureteral stents, prior pelvic surgery, and/or vascular disease.
- Ureteroarterial fistulae are difficult to diagnose radiographically with standard imaging, including CT scan and retrograde pyelography.
- Patients suspected of having a ureteroarterial fistula based on history and the presence of significant risk factors should be treated expeditiously and aggressively on presentation.

Oncologic and Radiation Fistulae

In the oncologic context, fistulae may occur as a result of primary or recurrent malignancy or as a consequence of cancer treatment by surgery, radiotherapy, chemotherapy, or a combination of therapies.

In one study, 536 women underwent a radical hysterectomy for invasive cervical cancer. More advanced stage of disease, obesity, diabetes, and postoperative surgical infection were predisposing factors to urinary tract complications. In this study, ureteral injury occurred in 1.32%, bladder injury in 1.49% with VVF forming in 2.61% and ureterovaginal fistula in 2.43% of cases, respectively (Likic et al., 2008). In a similar report, 1092 women with cervical cancer underwent a radical hysterectomy with obligatory pelvic lymphadenectomy. A VVF occurred in 0.3% and a ureterovaginal fistula occurred in 1.4% (Baltzer et al., 1980). The rate of GU injury likely varies between centers. For example, in one report of 479 women undergoing different methods of radical hysterectomy for cervical cancer over a 15-year period, 52 (10.8%) had urologic complications (17 bladder and ureter injuries, 35 fistulae and strictures) (Bostofte and Serup, 1981). In contrast, one institution reported that, with modifications and careful dissection, ureteric and bladder injury have almost been eliminated (Draca, 1979).

In two recently published case series, one of fistulae specifically associated with gynecologic cancers (Narayanan et al., 2009) and one of urogenital fistula from all causes (Hilton, 2011), those relating directly to primary cancer were uncommon (2/20 = 10% [Narayanan et al., 2009] and 2/348 = 0.6% *−2/66 = 3% of the oncologic cases in this series* [Hilton, 2011], respectively). Fistulae associated with cancer surgery (3/20 = 15% and 30/348 = 8.6%*−30/66 = 45% of the oncologic cases in this series*) or radiotherapy (15/20 = 75% and 34/348 = 9.8%*−34/66 = 52% of the oncologic cases in this series*) made up a much larger proportion of both series.

Immune deficiency may be a further contributory factor, and enterovesical fistula has previously been reported in association with non-Hodgkin lymphoma in HIV-AIDS (Genta et al., 1993), and vesicovaginal fistula has been seen in association with classical Hodgkin affecting the vagina in a long-term pessary user (Murdoch and Hilton, 2012).

Cancer Surgery

It is likely that all operations carried out in the pelvis can be complicated by genital tract fistula in some circumstances (Hilton, 2011). Operations carried out with the intention of curing malignant disease will inevitably carry a higher risk of subsequent fistula formation as compared with those undertaken with less radical intent.

After radical hysterectomy for cervical cancer (Wertheim-Meigs procedure) the rate of fistula formation reported from case series is between 0.6% and 4.4% (Averette et al., 1993; Hallum et al., 2000; Hatch et al., 1984; Jones et al., 1984; Likic et al., 2008; Ralph et al., 1990; Riss et al., 1988). These data are heterogeneous, some reporting all types of fistula together. Where they are reported separately, the rates of vesicovaginal and ureterovaginal fistula appear to be of the same magnitude with both being reported in between 0.9% and 2.5% of cases (Chen et al., 2008; Likic et al., 2008; Yan et al., 2009). The data from UK cited above suggests a urogenital fistula rate of 1 in 95 after radical abdominal hysterectomy in women with malignant disease as compared with 1 in 540 for total (simple) abdominal hysterectomy for benign disease, and 1 in 2041 for vaginal hysterectomy for all benign disease (including prolapse) (Hilton and Cromwell, 2012). Overall, the rate of urogenital fistula appears to be approximately 9 times higher after radical hysterectomy in women with malignant disease as compared with that after simple hysterectomy (abdominal or vaginal) in women with benign conditions (Hilton and Cromwell, 2012).

The risk of visceral injury or subsequent fistula formation after radical hysterectomy undertaken in pregnancy, or immediately after cesarean section is not obviously increased over those carried out electively in nonpregnant individuals. Monk and Montz (1992) described inadvertent cystotomy followed by vesicovaginal fistula in 1 of 21 women operated on during or immediately after pregnancy.

Several modifications to the conventional Wertheim-Meig procedure of radical hysterectomy have been described in an effort to reduce the associated morbidity. None of them seems to offer a benefit regarding fistula formation (Blythe et al., 1988; Bostofte and Serup, 1981).

Given the increased risk associated with radical surgery for malignancy, it is intuitive that the risks would increase with the stage of disease and with the extent of the surgery undertaken. There are few published reports of fistula after exenterative surgery. One study noted a 16% vesicovaginal fistula rate in 19 women after exenteration for vulvar carcinoma (Hopkins and Morley, 1992), whereas another describes a 15% bowel fistula rate and an 8% urinary fistula rate from a series of 75 exenterations for recurrent cervical cancer (Berek et al., 2005). In contrast, Ungar et al. describe only one ureterovaginal fistula and one pouch–vaginal fistula in 212 women undergoing exenteration out of a total of 2540 women treated for cervix cancer in 1 center over a 13-year period (0.9%) (Ungar et al., 2008).

Bladder-sparing techniques during pelvic exenteration can carry a risk for fistula formation (Liedl et al., 2014). Also when the bladder has been removed and a neo-bladder has been constructed, fistulae between the neo-bladder and the vagina may occur (Bailey et al., 2016; Carmel et al., 2016).

The introduction of laparoscopic surgery within oncology is seen to have considerable advantages in terms of patient recovery; the risk of operative injury to bowel and the urinary tract, and subsequent fistula formation may, however, remain a concern in such cases. Although some studies, case series, and nonrandomized cohorts describe similar rates of injury to those described after open radical surgery (Chen et al., 2008; Langebrekke et al., 2002; Marchiole et al., 2007; Xu et al., 2007; Yan et al., 2009), others have reported injury or fistula rates several times higher after laparoscopic radical hysterectomy (Hallum et al., 2000; Kadar and Reich, 1993).

The risk of urinary tract injury from minor surgical interventions is, in general, low, although the use of repeat procedures may confer a significant increase in risk. Vesicovaginal fistula has been reported after repeated use of CO_2 laser for vaporization of vaginal condylomata (Colombel et al., 1995) and after cone biopsy of the cervix (Nwabineli and Davis, 1992). In 1 personal series of 370 urogenital fistulae, 4 were associated with large loop excision of the transformation zone (LLETZ) of cervix, 3 of which followed a second LLETZ procedure (Hilton, personal communication).

Rarely, localized malignancies have been associated with VVF. One example is a primary mixed müllerian vaginal tumor reported in a 48-year female (Ahuja et al., 2011). The mechanism for fistula formation is likely to be direct invasion into the bladder.

Genitourinary injuries during colorectal surgery are rare. Eswara et al. (2015) described 75 GU injuries in 42570 colorectal surgeries: cystotomy (35%), incomplete ureteral transection (29%), ureteral injuries (15%). Preoperative external beam radiotherapy or chemotherapy and delayed repair were associated with worse outcome (Eswara et al., 2015).

Radiation Fistulae

Pelvic irradiation can be delivered by external beam as well as locally (intracavitary/brachytherapy). Fistula formation appears to be slightly higher for postoperative external radiation (1.9%) compared with intravaginal brachytherapy (0.8%) (Kucera et al., 1984). It does not appear that pretreatment factors accurately predict those who will develop fistula related to radiotherapy (Biewenga et al., 2010). **The three most common locally advanced malignancies that result in VVF include cervical, vaginal, and endometrial carcinoma, which in aggregate account for approximately 3% to 5% of VVFs in the industrialized world. Treatment of vaginal cancer is associated with a high complication rate;** up to 30% of patients develop significant complications including rectovaginal fistula or VVF, grade III to IV proctitis, cystitis, and vaginal stricture (Gunderson et al., 2013).

The literature in this area is particularly heterogeneous, with wide variation in (and some lack of clarity over) the tumor type and stage being treated, the form of radiation, and the site and dose delivered. In a series of urogenital fistulae from the UK, 34 of 348 or 9.8% were associated with previous radiotherapy; of those related to gynecologic cancer, 34 of 66, or 52%, had undergone radiotherapy (Hilton, 2011). In a further series of cases specifically related to gynecologic malignancy, 15 of 20, or 75%, had undergone previous radiotherapy (Narayanan et al., 2009). In both series most cases followed radiation used for the treatment of cervical cancer, although, 5 of 34, or 15%, followed treatment of endometrial cancer, and 1 of 34, or 3%, followed treatment of a multifocal gynecologic cancer in 1 series (Hilton, 2011). Among a series of 216 radiation-induced fistulae, the time to diagnosis of the fistula was made between 3 months and 10 years (mean 21 months) after radiation (Pushkar et al., 2009). In other series fistulae have been reported to develop or present up to 30 years after the “causative” influence (Hilton, 2011; Zoubek et al., 1989).

The incidence of any deleterious clinical impact on the gastrointestinal and urinary tracts after radiation varies in the literature between 1% and 12% (Cochrane et al., 1981; Demanes et al., 2000; Denton et al., 2002; de Crevoisier et al., 2007; Emmert and Kohler, 1996; Krause et al., 1987; Maier et al., 1997; Monk et al., 1994), with fistula rates of 1% to 5% (Angioli et al., 2003; Narayanan et al., 2009). In a retrospective review of 2096 patients treated for cervical cancer over a 10-year period using unspecified regimen(s) of radiotherapy, 38 patients (1.8%) were found to have developed fistulae, all of whom had stage IIIa/b or IV disease at presentation (Emmert and Kohler, 1996). Of these cases, approximately three-fourths involved the rectum, with one-third being combined rectovaginal and vesicovaginal fistulae; one-fourth were vesicovaginal only (Emmert and Kohler, 1996).

Following a clearly defined regimen of external beam radiation plus brachytherapy for the treatment of primary squamous cell carcinoma of vagina in 91 women, de Crevoisier et al. reported 10.0% grade 2 to 3 urinary tract toxicity (using the Franco-Italian glossary) (Chassagne et al., 1993) and 12.1% grade 2 to 3 gastrointestinal toxicity (de Crevoisier et al., 2007). Unsurprisingly, they found anterior tumor location to be correlated with increased risk of bladder toxicity and decreased rectal toxicity. Two women in this series developed rectovaginal fistulae (2%) and one ureterovaginal fistula (1%) (de Crevoisier et al., 2007).

In a series of 10,709 women treated by telebrachytherapy (67.5 Gy) for a range of gynecologic cancers in 1 center over a 22-year period, 133 (1.2%) developed urologic complications of which 35 (0.3%) developed fistulae (Maier et al., 1997).

In a series of 28 women treated by brachytherapy for recurrent corpus or cervix cancer, four patients developed chronic morbidities related to treatment. Three fistulae were reported in two patients (7.1%): one combined rectovaginal and vesicovaginal fistula and one ureterointestinal fistula; a further patient developed a ureteric stricture and small bowel obstruction requiring resection (Monk et al., 1994).

These data tend to suggest a higher rate of fistula formation after the application of radiotherapy in locally recurrent disease than in primary disease. From a small series of urologic complications after radiotherapy for gynecologic cancers, 14 patients had developed vesicovaginal fistula; of these, 4 (29%) had evidence of tumor recurrence (Krause et al., 1987). In the series reported by Jones at al. (1984) 326 of 1161 (28%) developed urologic complications over a 20-year period; 46 developed fistulae (4%), of whom 33 (72%) had evidence of active malignant disease.

In prostate cancer patients, recto-urethral fistula are described after cryotherapy (0.1%–4%) (Shah et al., 2014), HIFU (0.7%) (Ganzer et al., 2013), and brachytherapy (2%) (Park et al., 2013).

When a fistula occurs after radiotherapy, it is considered good clinical practice to exclude tumor recurrence before attempting a fistula closure. Feddock et al.

(2014) found 27 fistulae in 325 patients after post-radiation biopsies for cervical cancer. The fistula were toxicity-related in 51.9%, a consequence of primary disease in 22.2% and of recurrent disease in 25.9%. The residual or recurrent cancer found in the biopsies was only 31.5%. Elevated radiotherapy doses to the rectum, advanced tumor stage, and post-radiotherapy biopsy were considered risk factors for fistula formation.

Injury to the GI or urinary tract may arise after therapeutic radiation, with the incidence of complications increasing when the dose exceeds 50 Gy. The obliterative endarteritis associated with ionizing radiation in therapeutic doses may proceed over many years and may result in fistula formation long after the primary malignancy has been treated (Hilton, 2012). The associated devascularization in the adjacent tissues means that conventional surgical repair has a high likelihood of failure and may also result in re-presentation with several fistulae over a period of many years. If abdominal repair surgery or urinary diversions are undertaken, a high risk of GI anastomotic leak and progressive sepsis has been reported, perhaps related either to inadequate resection of irradiated bowel or to damage to other organs at operation (Cochrane et al., 1981). All these factors often make the management of postradiation fistulae more challenging than that of postsurgical or even obstetric fistulae. Modified surgical techniques are often required, and indeed, where the same techniques have been applied to surgical and postradiation fistulae, the results from the latter have been consistently poorer (Jovanovic et al., 2010). Spontaneous healing seems rarely if ever to occur (Hilton, 2012) and only one case report was identified, of presentation of a radiation fistula 22 years after initial treatment, in which healing occurred after cauterization (for biopsy) and prolonged catheter drainage (Madjar and Gousse, 2001). In some cases, hyperbaric oxygen therapy could be helpful, although there are no recent data to support this treatment option (Williams et al., 1992).

Management of Radiation Fistulae: Diversion Procedures

Because of the wide field abnormality surrounding many radiotherapy-associated fistulae, several authors have suggested that urinary and/or fecal diversion should be seen as the treatment of choice in such cases (Eswara et al., 2015; Langkilde et al., 1999; Lentz and Homesley, 1995). Others have employed a routine policy of preliminary urinary and fecal diversion, with later undiversion in selected cases (Vanni et al., 2010). In a nonrandomized cohort of rectourethral fistula repairs, Vanni et al. (2010) reported 100% closure at first operation in 35 nonirradiated patients, compared with 84% in 39 irradiated patients. In addition, 97% of the nonirradiated patients subsequently underwent undiversion, whereas 31% of the irradiated patients required permanent fecal diversion because of a noncompliant rectum or severe sphincter dysfunction (Vanni et al., 2010).

Some authors have emphasized the place of repair in carefully selected cases of radiotherapy-associated fistulae (Hilton, 2012). Of 36 radiation-associated or malignant fistulae in the series reported by Hilton, although 11 patients declined surgery or died before treatment and 6 underwent primary diversion, of the 19 (53%) who underwent repair, closure was achieved in 18 (95%) at first operation (Hilton, 2012). Finally, some authors seem to take the view that diversion has little or no place in the management of radiation-induced VVF in particular (Pushkar et al., 2009). Of 216 radiation-induced fistulae managed over a 47-year period by Pushkar et al. (2009), 210 patients underwent a vaginal and 6 an abdominal repair procedure (this is a retrospective case series, and although not stated in the paper, it is possible that other patients not included in this review actually underwent diversion). However, with this almost exclusive use of the vaginal repair procedure, although a cumulative closure rate of 80% was eventually achieved after four or more operations, closure was achieved in only 48% after first repair, in 40% after a second operation, in 52% after a third operation, and in 35% after a fourth operation.

In view of the anastomotic problems associated with radiation-induced fistula, the transverse colon has often been favored over ileum as a conduit in this context to avoid the risk of employing irradiated bowel and distal ureter (Schmidt and Buchsbaum, 1986). Although these benefits seem clear, high perioperative morbidity (37%) and reoperation rates (20%) have been reported from this procedure (Ravi et al., 1994).

As an alternative to the latter operation, wherein urinary and fecal diversion are proposed, Hampson et al. (1994) described the technique of left colic urinary diversion with distal transverse end colostomy. This technique allows a shorter operative time and avoids the necessity for an intestinal anastomosis. In patients wishing to remain sexually active after such procedures, the residual bladder or rectal wall may be used to augment the vagina (Leissner et al., 2000). Where VVF coexists with significant bladder contracture after surgery or radiation, an abdominal (transperitoneal) repair may be considered, along with simultaneous ileocystoplasty or coloplasty (Mao et al., 2017; Mayersak et al., 1995, Tabakov and Slavchev, 2004). Fistula repair performed concurrently with vaginal reconstruction using sigmoidovaginoplasty has also been described by Verbaeys et al. (2007). Although one may anticipate very high operative and postoperative morbidity from such complex multiple procedures, the outcome in the very small numbers reported appears to have been good.

Management of Radiation Fistulae: Repair Techniques

Several different techniques for the vaginal repair of fistulae have been reported, although the methods of flap-splitting or dissection and repair in layers (variously attributed to Hayward, Collis, and Lawson Tait) (Wall, 2005) and partial colpocleisis (Latzko, 1942) have been the most widely advocated in radiation-associated fistulae. When patients do not wish to maintain sexual function, complete colpocleisis may be used to good effect (Hilton, 2012). In a nonrandomized cohort study, Hilton (2012) reported anatomic closure by colpocleisis in 94.7% of patients with radiation-associated fistulae, compared with 96.1% for a range of repair procedures in fistulae of surgical cause.

The technique of sigmoid exclusion or isolation has been described for the management of radiation-associated colovesical or enterovesical and colovaginal or enterovaginal fistulae (Levenback et al., 1994). Although the results have generally been good, with the avoidance of a permanent urinary or fecal stoma, Levenback et al. (1994) reported poorer results than after resection of the affected bowel, largely related to bleeding from the isolated segment and bacterial infection.

The interpositional grafts mentioned earlier are particularly useful in radiation-induced fistulae.

Other Management Approaches

In patients with intractable urinary incontinence from radiation-associated fistula, percutaneous nephrostomy or ureterostomy may be considered (Krause et al., 1987). This may in some cases extend life perhaps inappropriately, and where life expectancy is deemed to be very short, ureteral occlusion may be more appropriate. Several methods have been described, including the insertion of coils (Amsellem-Ouazana et al., 2006) and other devices (Asvadi and

Arellano, 2015; Kim et al., 2008; Pieper et al., 2014). These were reviewed by Avritscher et al. (2004) with success rates ranging from 50% to 100% for the different methods, and with an overall success rate of 77% in 150 cases from 9 papers reviewed.

Recommendations

Although diversion is used more widely in radiation-associated fistulae of all types as compared with nonirradiated fistulae, there is low-level evidence that repair procedures can achieve successful fistula closure and continence in appropriately selected cases.

Where urinary and/or fecal diversions are required, attempts should be made to avoid using irradiated tissues whenever possible and to minimize the potential for anastomotic complications.

There is low-level evidence to support the use of interpositional grafts when repair of radiation-associated fistula is undertaken.

In patients with intractable urinary incontinence from radiation-associated fistula in whom life expectancy is very short, ureteral occlusion may be considered; there is insufficient evidence to recommend any particular technique.

Chemotherapy

There are few reports of fistula formation in association with the use of chemotherapy. One case report described a patient who developed a vesicovaginal fistula having undergone abdominal hysterectomy for atypical endometrial hyperplasia while taking *tamoxifen* after a previous modified radical mastectomy. Surgical repair of the fistula was initially unsuccessful, although after discontinuing the *tamoxifen* and continued bladder drainage, healing occurred (Caputo and Copeland, 1996). It was hypothesized that the impaired healing was a result of the administration of the hormone therapy.

Combination Therapies

Adjuvant or neoadjuvant therapies are used to increase the efficacy of the primary treatment compared with its use in isolation. It may be anticipated that this would also increase the range and magnitude of adverse effects.

In a case control study examining the urinary tract complications of radical hysterectomy only a single vesicovaginal fistula was seen in 50 patients (2%), in a patient receiving preoperative irradiation (45–50 Gy) (Behtash et al., 2005). A small case series found 2 of 20 or a 10% rate of urinary fistulae after preoperative irradiation and radical hysterectomy in a heterogeneous group of “high-risk” cervix cancers (Monk et al., 1993). A further case series described the impact of combined external whole pelvic irradiation (50 Gy) and intravaginal cone boost (20–26 Gy) after radical hysterectomy in 108 women. The overall rate of fistula formation was 3.7%, 2.2% after “prophylactic” radiation, and 10.5% in “salvage” cases in which recurrent disease was present (Mitsuhashi et al., 1995).

Modarress et al. (2005) reported a randomized comparison of preoperative combined chemoradiation (cisplatin plus external beam therapy) and neoadjuvant chemotherapy (cisplatin plus vincristine) followed by radical hysterectomy in stage IB-IIB bulky cervical cancer. Four patients developed hydronephrosis (3 in the chemoradiation group, 13.3%) and two vesicovaginal fistula (both in the chemoradiation group, 6.7%) (Modarress et al., 2005). Two further case series reported 2 of 36 or a 5.6% rate of fistulae after preoperative chemoradiation (cisplatin plus brachytherapy) followed by radical hysterectomy (Koumantakis et al., 1998), and 4 of 46 or 8.7% rate of fistulae after the use of neoadjuvant and postoperative chemotherapy using irinotecan, cisplatin, and nedaplatin (Matsumura et al., 2010). In a recent series of chemoradiotherapy for cervical cancer, fistula were reported in only 1.6% of cases (Jakubowicz et al., 2014).

Other Urinary Fistulae

Urinary fistulae have been reported between the kidneys and thoracic cavity with a number of causes, including infection, trauma, and stone disease. Infectious causes include xanthogranulomatous pyelonephritis, TB, and renal abscess (Arida, 1977; Blight, 1980; Liu et al., 2016). Fortunately, nephropleural and nephrobronchial fistulae are uncommon. **Percutaneous access to the kidney for endourologic procedures may be complicated by nephropleural fistula** (Hyatt et al., 2017). Lallas et al. (2004) reported a 1% incidence of nephropleural fistulae in 375 patients undergoing percutaneous access procedures. All of the affected patients had a supracostal access tract performed; none of the patients with a subcostal access tract developed this complication. Presenting symptoms may include cough, a urine-like taste in the mouth, fever, and flank pain.

Treatment of nephropleural or nephrobronchial fistulae typically involves percutaneous drainage of any associated abscess (if present), treatment of associated infection and/or urinary obstruction, and surgical exploration with interposition of healthy tissue. **Iatrogenic fistulae resulting from percutaneous access procedures can be managed nonoperatively in some cases** (Lallas et al., 2004). **Nephrectomy is indicated in poorly functioning renal units.**

Cutaneous fistulae from the urinary tract may arise from the kidney, ureter, bladder, or urethra. Renocutaneous fistulae may occur as a result of chronic infection, especially in the setting of calculous disease (Haney et al., 1992). Often the associated renal unit is poorly functioning, and thus definitive treatment is provided by nephrectomy. External trauma or iatrogenic surgical trauma, such as percutaneous renal surgery or partial nephrectomy, may also result in a renocutaneous fistula. Prompt treatment with internal ureteral stenting is usually successful by providing unobstructed antegrade urinary drainage. Most ureterocutaneous and vesicocutaneous fistulae are iatrogenic or otherwise purposefully surgically created to facilitate urinary drainage. Other uncommon causes include external penetrating trauma, malignancy, and chronic infection.

For newly diagnosed urocutaneous fistulae, it is imperative to evaluate for distal urinary obstruction. If present, the obstruction should be treated, if possible, or bypassed. **Individuals with nonhealing urocutaneous fistulae caused by chronic infection not only should be evaluated for an occult source of the infection but also should undergo a nutritional evaluation**

because these individuals may be catabolic, immunosuppressed, and unable to mobilize adequate metabolic reserves to initiate wound closure. Other considerations in individuals with nonhealing urocutaneous fistulae include occult malignancy or an undiscovered foreign body.

Urinary Leak After Renal Preservation Surgery

A large case series identified urinary fistula, defined as urinary drainage from a drain site more than 14 days postoperatively, in 4% (45 of 1118) of patients undergoing partial nephrectomy (Kundu et al., 2010). This was associated with larger tumors, greater blood loss, and longer ischemia time, but not the mode of surgery (laparoscopic vs. open). The majority resolved without intervention, but 30% required ureteral stent insertion or percutaneous drainage. A poor-quality quasi-randomized study involving 16 patients with persistent leakage after pelvicalyceal surgery despite stenting found that use of intranasal desmopressin 40 µg daily resulted in a shorter time to resolution of leak compared with controls (Razzaghi et al., 2009).

Urinary Leak After Renal Transplantation

A case series from Brazil observed a fistula rate of 3.0% (31 of 1046) at a mean of 28 (1 to 131) days after transplantation predominantly as a result of distal ureteral necrosis and with most cases requiring open repair (Mazzucchi et al., 2006). Fistula occurred more commonly in patients with diabetes and was associated with lower graft survival and 2 deaths from sepsis. A case series from China observed fistula development in 3.5% (43 of 1223) of patients at a mean of 6 (range 3 to 20) days after transplantation, again primarily a result of necrosis of the distal transplanted ureter (Nie et al., 2009). Open intervention with reimplantation of the ureter into the bladder or native ureter was required in 34 patients, with 1 other patient requiring transplant nephrectomy. The occurrence of a fistula did not appear to prejudice graft or patient survival. Initial implantation of the transplant ureter into the native ureter appeared to result in a lower rate of fistula. A further case series from Serbia found a fistula rate after renal transplantation of 2.2% (5 of 224), and all required open repair (Basic et al., 2011).

See Videos 129.1 to 129.4 for procedures related to this chapter.

Key Points: Other Fistulae

- Nephropleural or nephrobronchial fistulae are uncommon and may occur secondary to percutaneous access procedures to the upper urinary tract.
- Urocutaneous fistulae may originate from multiple locations within the urinary tract.

Acknowledgments

The authors are grateful to Gopal H Badlani, MD, FACS, Jayadev Reddy Mettu, MD, MBBS, and Eric S. Rovner, MD, who co-authored the previous edition of this chapter with D. De Ridder. Much of their text and illustrations have been used.

Bladder and Female Urethral Diverticula

Lindsey Cox MD, Eric S. Rovner MD

Bladder Diverticula

The term *bladder diverticulum* is usually reserved for a subjectively large herniation of the bladder urothelium through the muscularis propria of the bladder wall. This results in a thin-walled, urine-filled structure adjacent to and connecting with the bladder lumen through a variably sized neck, or ostium. Histologically **the diverticulum wall is composed of mucosa, subepithelial connective tissue or lamina propria, some scattered thin muscle fibers, and an adventitial layer** (Fig. 130.1) (Gil-Vernet, 1998; Peterson et al., 1973). A **fibrous capsule or pseudocapsule outer shell is often present and may be a useful surgical plane for excision**. The outside wall of the bladder diverticulum often contains some residual scattered strands or bundles of smooth muscle; however, these are disorganized and nonfunctional. Therefore bladder diverticula generally empty poorly during micturition, leaving a large postvoid residual urine volume that results in the characteristic findings on presentation and imaging.

Classification, Pathophysiology, and Etiology

Bladder diverticula may occur in adults or children, but overall approximately

90% of bladder diverticula occur in adults (Psutka and Cendron, 2013). In addition, these lesions are far more common in males than females, with a ratio of approximately 9 : 1 in the adult and pediatric age groups (Idrees et al., 2013).

Bladder diverticula may be classified as either congenital or acquired. Pathophysiology, presentation, clinical implications, and imaging may differentiate these two types. **Congenital diverticula usually are seen during childhood, with a peak incidence in those younger than 10 years old** (Boechat and Lebowitz, 1978). **These are usually solitary, occur most commonly in males** (Evangelidis et al., 2005; Garat et al., 2007; Idrees et al., 2013; Sarihan and Abes, 1998; Stage and Tank, 1992), **and are located lateral and posterior to the ureteral orifice, often in association with vesicoureteral reflux** (Evangelidis et al., 2005; Garat et al., 2007). **In contrast to adults, in whom coexistent lower urinary tract neurogenic dysfunction or obstruction is almost always present, the primary causation in the pediatric age group is generally thought to be a congenital weakness of the detrusor muscle, most often at the level of the ureterovesical junction with or without coexistent lower urinary tract abnormalities** (Hutch, 1961; Hutch et al., 1961; Johnston, 1960; Psutka and Cendron, 2013; Stephens, 1979). Approximately 90% of pediatric or congenital bladder diverticula occur in the vicinity of the ureterovesical junction (Psutka and Cendron, 2013). Congenital bladder diverticula may occur in the presence of normal voiding dynamics in the absence of bladder outlet obstruction (Barrett et al., 1976; Blane et al., 1994; Cendron et al., 1972); however, up to 60% of congenital bladder diverticula may be associated with an underlying syndrome, neuropathic voiding dysfunction, or outlet obstruction (Blane et al., 1994). Blane et al. (1994) reported the incidence of bladder diverticula in children to be approximately 1.7% in a pediatric genitourinary database of more than 5000 cases. Congenital bladder diverticula are usually relatively larger in comparison with those associated with obstruction or neurogenic bladder dysfunction (Gearhart, 2002).

The most common presentation of congenital bladder diverticula is acute urinary tract infection (UTI) resulting from stasis (Bauer and Retik, 1974; Evangelidis et al., 2005; Garat et al., 2007; Pieretti and Pieretti-Vanmarcke, 1999). Less common presentations include enuresis, pyelonephritis, acute retention, and stones. Notably, secondary bladder outlet obstruction may occur when the diverticulum extends distally toward the bladder neck (Epstein et al., 1982; Oge et al., 2002; Taylor et al., 1979; Verghese and Belman, 1984). **Typically, congenital bladder diverticula are found in smooth-walled**

bladders and are not associated with significant trabeculation on cystoscopic examination (Hutch, 1961). In patients with prune-belly syndrome or posterior urethral valves, bladder diverticula may be located at the dome and be associated with aberrant voiding dynamics and/or anatomy. These are to be distinguished from the urachal diverticula seen in some pediatric urologic conditions. **Importantly, unlike secondary or adult bladder diverticula, there is almost no increased association with malignancy in congenital diverticula** (Alexander et al., 2012; Idrees et al., 2013; Tamas et al., 2009).

Congenital bladder diverticula have been noted in association with a number of congenital syndromes, including Menkes syndrome (kinky hair or copper deficiency syndrome) (Daly and Rabinovitch, 1981; Harcke et al., 1977; Hebert and Martin, 2015), Williams syndrome (Babbitt et al., 1979; Blane et al., 1994; Schulman et al., 1996), Ehlers-Danlos syndrome (Bade et al., 1994; Breivik et al., 1985; Burrows et al., 1998; Cuckow et al., 1994; Levard et al., 1989; Rabin et al., 1991; Schippers and Dittler, 1989), and fetal alcohol syndrome (Lewis and Woods, 1994). Whether there is a genetic predisposition to the formation of bladder diverticula in individuals without congenital syndromes is unclear, although congenital bladder diverticula have been reported in twins (Beall and Berger, 1978) and possibly as an autosomal dominant trait in a family (Hofmann et al., 1984). Because of the association of congenital bladder diverticula with genetic syndromes, it has been suggested that chromosomal testing should be pursued in such patients (Blane et al., 1994); however, this testing is generally not recommended in children with a single simple lesion (Hebert and Martin, 2015; Psutka and Cendron, 2013).

Acquired (also termed “secondary”) diverticula occur most commonly in the setting of bladder outlet obstruction or neurogenic vesicourethral dysfunction. Similar to the congenital type, these diverticula are located most commonly at the ureterovesical hiatus (Van Arsdalen and Wein, 1992) but also occur elsewhere in the bladder. **Acquired diverticula in males usually occur after age 60, which corresponds to the age of the development of prostatic enlargement** (Fig. 130.2). Bladder outlet obstruction (including that resulting from benign and malignant disease of the prostate), bladder neck obstruction (e.g., bladder neck hypertrophy, bladder neck contracture), and urethral stricture are commonly associated factors in adults, although obstruction is not considered to be present in all cases (Blacklock et al., 1983). Approximately 70% of bladder diverticula are associated with benign prostatic hyperplasia (Gerridzen and Futter, 1982). Historically, the reported prevalence of moderate-to large-sized bladder diverticula in association with "prostatism" is approximately 1% to 6% (Burns, 1944). **Acquired diverticula are often multiple, typically found in association with significant bladder trabeculation** (Wesselhoeft et al., 1963), **and much more common in males than females** (Pool and Hacker, 1966; Senger et al., 1952). Bladder diverticula in females are relatively uncommon and often associated with bladder outlet obstruction (Gillon et al., 1988). When found in the female, careful evaluation of the bladder outlet often reveals a cause for obstruction such as dysfunctional voiding, vaginal prolapse, bladder neck hypertrophy, urethral stricture, or iatrogenic obstruction resulting from anti-incontinence surgery (Safir et al., 1998; Fig. 130.3). Acquired bladder diverticula may also be found in children and young adults secondary to a number of conditions, including bladder neck dysfunction, posterior urethral valves, and neurogenic vesicourethral dysfunction. **If the diverticulum is located superolateral to the ureteral orifice, without involving the trigone in the setting of a neuropathic bladder and vesicoureteral reflux, it is termed a "Hutch" diverticulum, named after the individual who described this finding in a series of paraplegic individuals** (Hutch, 1952). These diverticula may also occur in the setting of dysfunctional voiding.

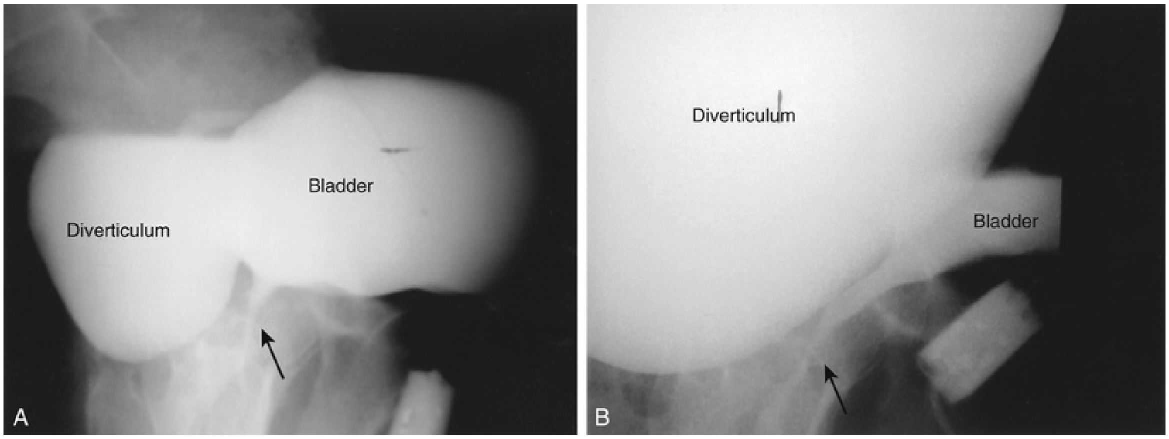

FIG. 130.2 Voiding cystourethrogram (VCUG) demonstrating a bladder diverticulum in a male. (A) The diverticulum is seen posterior to the bladder on this lateral voiding image (*arrow* points to urethra). There is a fluid-fluid level within the diverticulum representing the relatively denser contrast media settling below the urine. (B) Later image from the VCUG demonstrates near emptying of the bladder with enlargement of the diverticulum (*arrow* points to urethra).

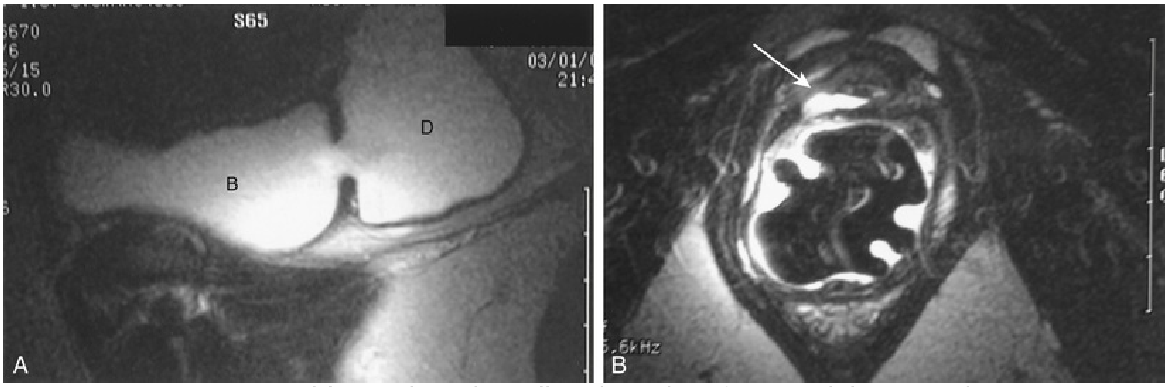

FIG. 130.3 Bladder and urethral diverticula in a female. (A) Magnetic resonance imaging (MRI) of a bladder *(B)* diverticulum *(D).* (B) Endoluminal MRI demonstrating urethral diverticulum (*arrow* points to urethral diverticulum).

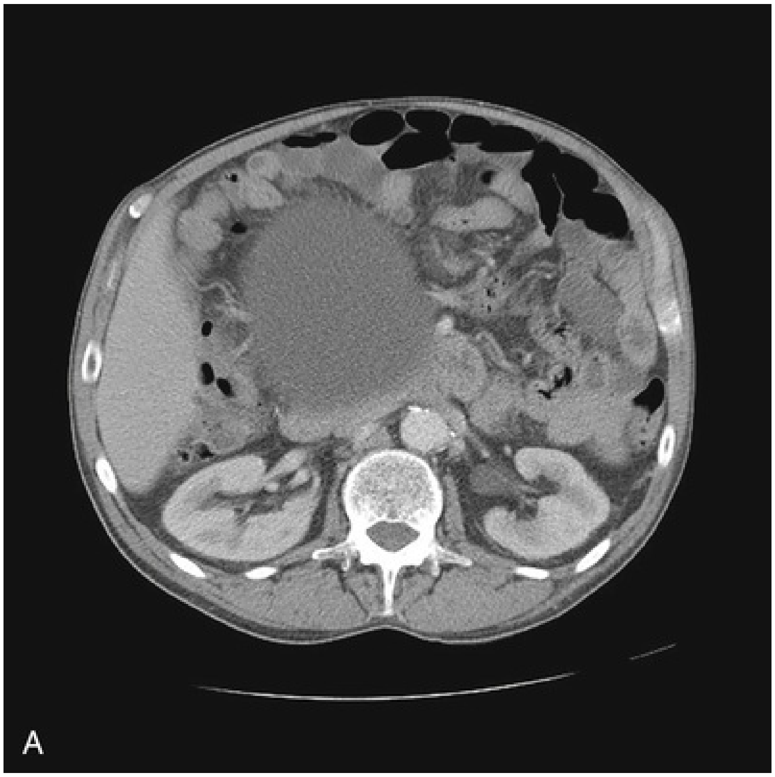
Bladder diverticula may also be iatrogenic (Chertin and Prat, 2008; Hernández et al., 1997; Suzuki et al., 2002). Inadequate closure of the muscular layers of the bladder wall after a cystotomy for any indication may result in formation of a bladder diverticulum at a weak point of the suture line. “Iatrogenic” bladder diverticula may also occur after ureteral reimplantation surgery at the ureteroneocystostomy site (Ahmed et al., 1982; Sheu et al., 1998).

Diagnosis

Presentation and Evaluation

Acquired bladder diverticula do not typically produce specific symptoms and are most often found incidentally in the evaluation of other signs and symptoms, especially UTI (Fig. 130.4). Because large bladder diverticula empty poorly or incompletely during voiding, symptoms and signs, if present, are usually attributed to urinary stasis within the diverticulum or, alternatively, to its mass effect in the lower abdomen and pelvis. Retrospectively, when queried, patient symptoms such as incomplete bladder emptying, lower abdominal fullness, and double voiding may be attributed to some large bladder diverticula. These symptoms, however, are nonspecific and can be due to prostatic enlargement, obstruction, or a number of other lower urinary tract conditions. **Most bladder diverticula are found during the investigation of nonspecific lower urinary symptoms, hematuria, or infection—or, alternatively, noted incidentally during radiographic or endoscopic investigation of these conditions.** As noted previously, congenital bladder diverticula most often occur with UTI (Bauer and Retik, 1974; Evangelidis et al., 2005; Garat et al., 2007;

Pieretti and Pieretti-Vanmarcke, 1999), but hematuria, abdominal pain, or an abdominal mass may be present as well. Inguinal hernias containing bladder diverticula have also been reported (Bolton and Joyce, 1994; Buchholz et al., 1998; Scardino and Upson, 1953; Schewe et al., 2000).



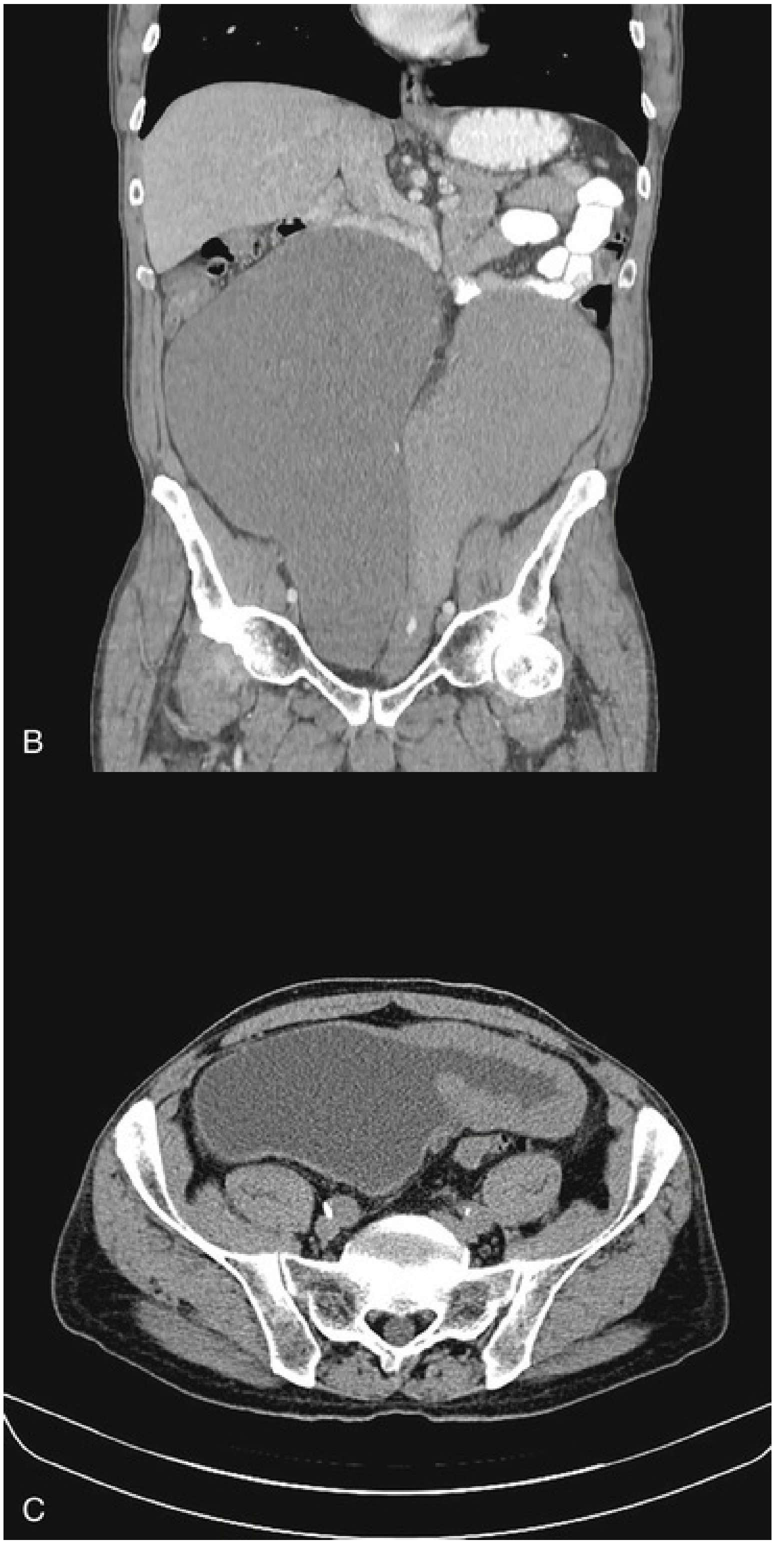


FIG. 130.4 Computed tomography (CT) scan of an enormous bladder diverticulum found initially on a CT scan of the chest in evaluation of pulmonary complaints. The patient had no lower urinary tract symptoms nor history of urinary tract infection. (A) CT chest scan showing fluid-filled structure below the diaphragm. (B) Coronal CT scan of abdomen/pelvis

showing fluid-filled structure. (C) Axial CT image showing partially distended bladder and pelvic viscera displaced by bladder diverticulum.

UTI in the male has been associated with bladder diverticula because it is often an infection in a male that provides the impetus for further clinical investigation uncovering a diverticulum. A bladder diverticulum and subsequent urinary stasis may result in a predisposition for UTI and may confer an increased difficulty in eradicating an existing infection (Shah, 1979; Taylor et al., 1979).

The initial evaluation of a bladder diverticulum includes a thorough history and physical examination, including digital rectal examination. In the male, prostate-specific antigen testing is pursued where appropriate. The history should quantitate lower urinary tract symptoms, query potential occult sources of neurogenic vesicourethral dysfunction (e.g., spinal surgery), and properly characterize any prior lower urinary tract surgery.

Urine analysis and urine culture as well as urine cytology should be considered in most patients with bladder diverticula, especially when nonoperative management is being considered. Abnormalities of the urine sediment are common in patients with bladder diverticula. Pyuria and hematuria are often present. In fact, relapsing or persistent pyuria unresponsive to antibiotic therapy may be an indication for bladder diverticulectomy in an otherwise asymptomatic patient. **The finding of a bladder diverticulum in an adult should prompt further evaluation for bladder outlet obstruction or occult neuropathic vesicourethral dysfunction, as well as endoscopic examination and imaging of the lower and upper urinary tract.**

Imaging

The diagnosis of bladder diverticula relies on radiographic and endoscopic findings. Bladder diverticula are part of the radiologic continuum that includes cellules and saccules. Cellules, saccules, and bladder diverticula are thought to represent increasingly larger and therefore more severe manifestations of the same pathological process involving elevated intravesical voiding pressure (Talner et al., 2000). **Cellules and saccules represent small outpouchings between hypertrophied bands of bladder muscle, with saccules generally being larger than cellules. However, there are no universally agreed upon minimum size requirements that distinguish cellules, saccules, and bladder diverticula, and the differentiation among these three entities is often**

subjective and arbitrary (Talner et al., 2000).

As noted previously, bladder diverticula are often found incidentally in the radiographic investigation of recurrent UTIs or other nonspecific lower urinary tract symptoms or signs. The differential diagnosis of a fluid-filled structure adjacent to the bladder is lengthy and includes müllerian cysts; uterine, ovarian, and fallopian tube abnormalities; urachal cysts; ectopic ureter or ureterocele; and postsurgical changes, including lymphocele.

Fluoroscopically monitored voiding cystourethrography (VCUG) is an excellent study to detect bladder diverticula; however, false negatives are possible (Hernanz-Schulman and Lebowitz, 1985). **A VCUG with anterior-posterior, oblique, and lateral images provides information regarding anatomy, location, and size of the diverticulum. It also assesses for associated vesicoureteral reflux and, importantly, evaluates for adequate emptying of the bladder diverticulum with voiding.** Vesicoureteral reflux may be found in up to 13% of patients with congenital bladder diverticula (Barrett et al., 1976). The finding of vesicoureteral reflux associated with bladder diverticula in the pediatric population has historically prompted ureteroneocystostomy in all cases; however, recently authors have pursued a more selective approach, reimplanting only those ureters associated with complicating factors such as renal scarring or progressive renal function deterioration (Afshar et al., 2005). Anomalous voiding into the diverticulum during a detrusor contraction may result in paradoxic enlargement of the bladder diverticulum during micturition (Wesselhoeft et al., 1963) (see Fig. 130.2). Presumably, this occurs during the detrusor contraction as the contrast flows from an area of relatively high pressure in the bladder through the diverticula ostia and into the diverticulum, which represents an area of relatively low pressure. In some instances the bladder may empty or discharge partly into the diverticulum and partly through the urethra. Often, with continued observation under fluoroscopy after the cessation of voiding, the empty bladder will start to refill as the diverticulum discharges back into the bladder. The amount of postvoid residual urine in the bladder diverticulum and bladder should be noted.

Cross-sectional imaging of the lower urinary tract may provide useful information regarding bladder diverticula and critical information regarding the surrounding anatomy. **Review of the radiographic films should accurately characterize the number, anatomy, and location of the diverticula as well as assess for masses within the diverticulum.** Filling defects within the diverticula or other bladder abnormalities should prompt further investigation

(Fig. 130.5). If the neck of the diverticulum is obstructed from a tumor or otherwise not patent, cross-sectional imaging may be required for diagnosis and further evaluation (Dondalski et al., 1993). Finally, cross-sectional imaging provides surgically relevant information, including the location of the ureters and surrounding structures (e.g., rectum), which can be distorted because of the space-occupying nature of some large bladder diverticula.

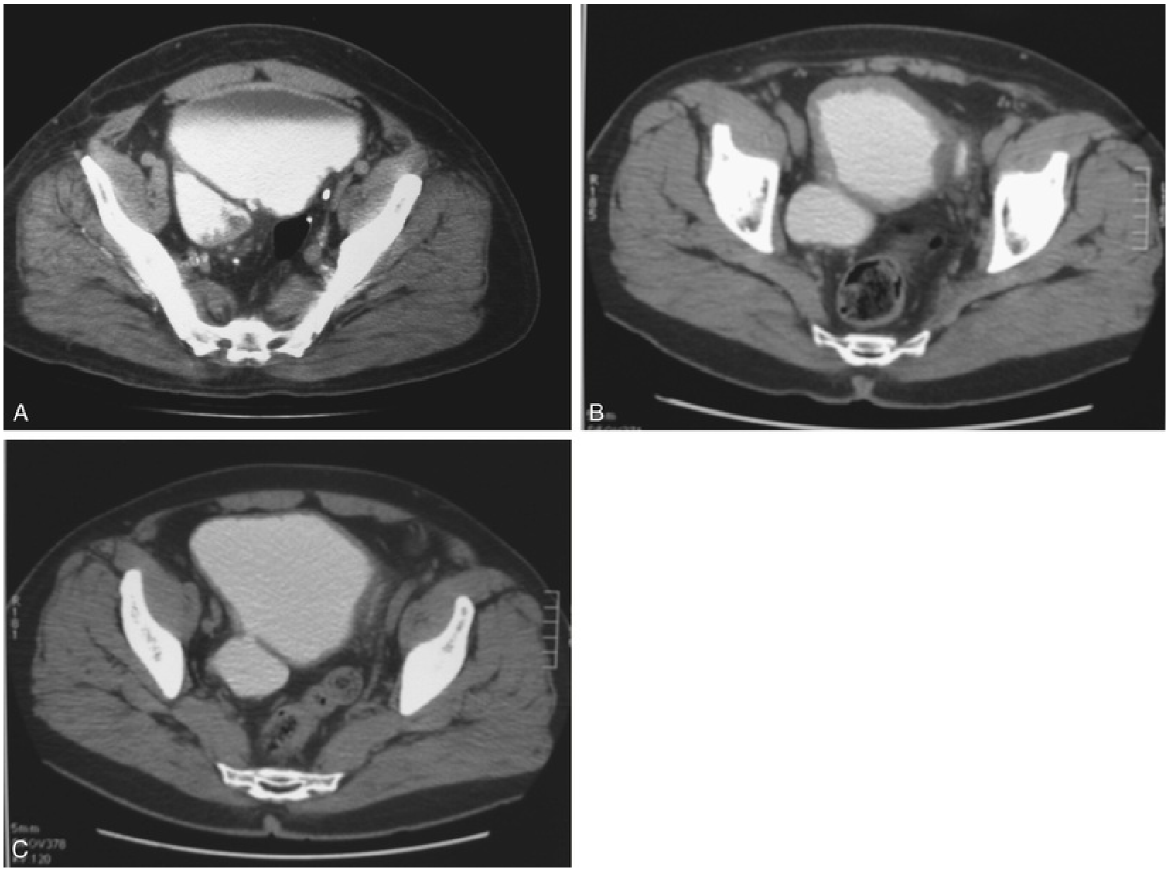

FIG. 130.5 Computed tomography (CT) scans demonstrating several abnormalities in the setting of a bladder diverticulum. (A) Diverticulum with multiple filling defects. Cystoscopy and biopsy revealed urothelial carcinoma. (B) Diffusely thickened and irregular bladder wall resulting from chronic bladder outlet obstruction in association with two diverticula. Cystoscopy confirmed trabeculation without mucosal abnormalities. (C) Asymmetrical bladder wall thickening in association with a bladder diverticulum. The ostium of the diverticulum is seen connecting to the bladder.

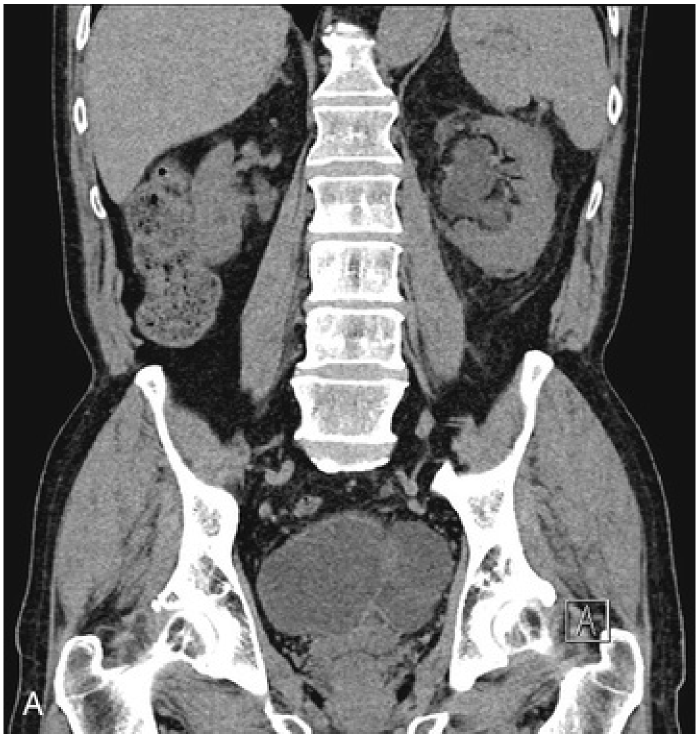
Imaging of the upper urinary tract may include intravenous pyelography, ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI). **In the absence of hematuria or a known or suspected urinary tract**

malignancy, the goal of upper tract imaging in the adult is to evaluate for asymptomatic or silent hydroureteronephrosis related to the diverticulum (Lebowitz et al., 1979; Sharma et al., 1997) which has been reported to be present in up to almost 7% of cases in one series (Fox et al., 1962). In children with bladder diverticula the reported incidence of upper tract abnormalities, including renal scarring, dysplasia, and hydronephrosis, has been reported to be as high as 30% (Gotoh et al., 1987; Tokunaka et al., 1980). Hydronephrosis may be related to obstruction of the ureter (Kwan and Lowe, 1992; Livne and Gonzales, 1985), an underlying urodynamic abnormality that resulted in the formation of the diverticulum, vesicoureteral reflux in association with the diverticulum, and inflammation (Bellinger et al., 1985), or may be completely unrelated to the bladder diverticulum (Fig. 130.6). A multichannel urodynamic study in combination with a VCUG or, alternatively, a video-urodynamic study is useful in this setting to differentiate upper from lower urinary tract causes of the hydronephrosis.



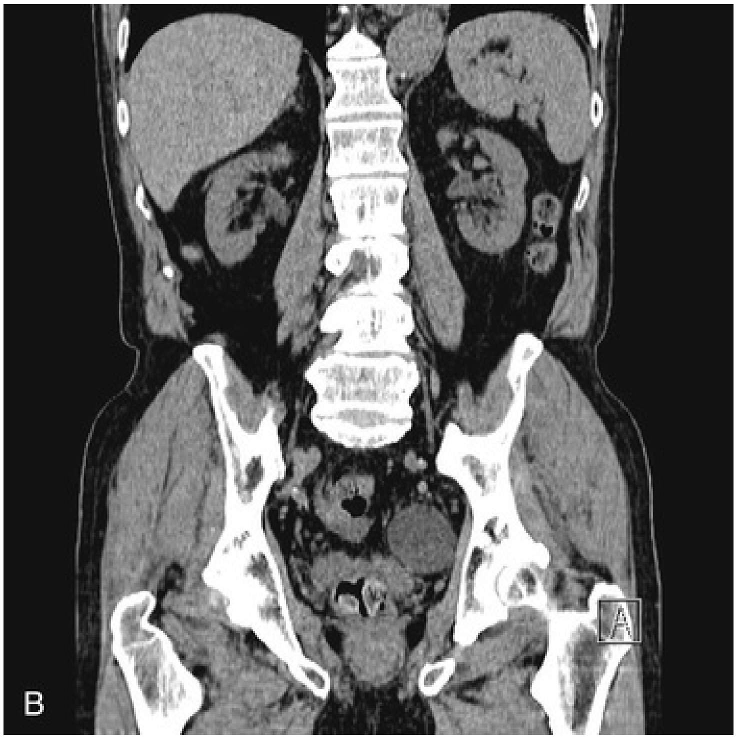


FIG. 130.6 Hydronephrosis related to a bladder diverticulum and bladder outlet obstruction. (A) Computed tomography scan of left-sided hydronephrosis related to ipsilateral bladder diverticulum and urinary retention. (B) Resolution of the hydronephrosis after treatment of the bladder outlet obstruction. The bladder diverticulum was persistent but smaller after transurethral resection of the prostate, which relieved the hydronephrosis.

A bladder diverticulum may cause deviation with or without compression of the ipsilateral ureter. **Medial deviation of the pelvic ureter is most commonly seen; however, lateral deviation may also occur** (Talner et al., 2000; Fig. 130.7). Such information is important in determining surgical approach and whether to place ureteric stents preoperatively. Furthermore, a bladder diverticulum that encompasses the ureteral orifice may create a functionally shortened intramural ureteral segment and result in vesicoureteral reflux (see later discussion).

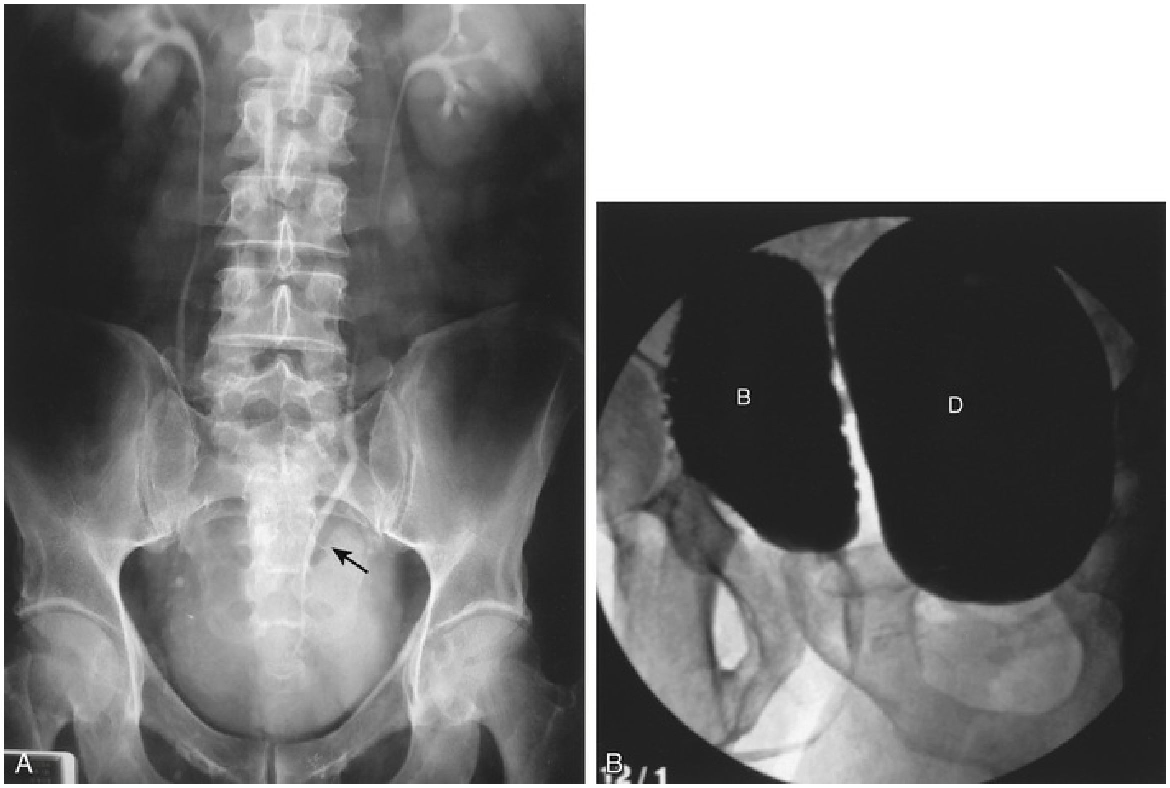

FIG. 130.7 Bladder diverticulum with deviation of the ureter. This patient had a long history of recurrent urinary tract infections as a result of presumed prostatitis. (A) Image from 10-minute intravenous urogram demonstrating medial deviation of the pelvic ureter *(arrow)*. (B) Voiding image from the voiding cystourethrogram revealed a large, smooth-walled bladder *(B)* diverticulum *(D)* emanating from the trabeculated bladder.

Urodynamics

In the adult, bladder outlet obstruction and/or neurogenic voiding dysfunction may result in the formation of bladder diverticula. A video-urodynamic study can be very helpful in the investigation of these patients (Adot Zurbano et al., 2005). The role of urodynamics in the evaluation of congenital bladder diverticula is less well defined (Psutka and Cendron, 2013). However, **failure to identify and treat an existing underlying urodynamic abnormality before or concomitantly with definitive surgical therapy for bladder diverticula, especially in an adult may result in a high risk of recurrent diverticula or other problems after surgery. Therefore such an evaluation is critical.** Furthermore, successful treatment of the urodynamic abnormality may improve bladder emptying and potentially result in resolution of the symptoms and/or complications without the need for bladder diverticulectomy.

Bladder outlet obstruction, impaired contractility, elevated postvoid residual urine, and detrusor overactivity are some of the urodynamic findings associated with bladder diverticula. Importantly, **bladder contractility may appear to be diminished on urodynamics because of the "pressure sink" effect of the bladder diverticulum.** This artifact occurs as the detrusor contracts and the intravesical contents are decompressed through the path of least resistance into the bladder diverticulum as opposed to the urethra (Wilson and Klufio, 1985). Nevertheless, when carefully measured, bladder contractility is not significantly different from that in individuals with benign prostatic hyperplasia without bladder diverticula (Adot Zurbano et al., 2005). In addition, elevated postvoid residual urine may be present as a result of retained urine in the diverticulum regardless of the presence or absence of impaired bladder contractility or bladder outlet obstruction.

Endoscopic Examination

Endoscopically, the entire interior of each bladder diverticulum should be thoroughly inspected for stones or abnormal-appearing epithelium. Flexible cystoscopy is often required to examine the entire interior of some diverticula. The location of the diverticula relative to the ureters and bladder outlet is noted, and the size of each diverticulum is carefully recorded (Fig. 130.8). Ideally, urine cytology should be obtained from the diverticulum during endoscopic examination. **Any abnormal-appearing epithelium or lesions within the diverticulum are carefully biopsied** (Fig. 130.9)**. Extreme care must be taken during the biopsy to prevent perforation, because the wall of the diverticulum is very thin because of the lack of a muscularis propria layer. All epithelial lesions under consideration for biopsy should be considered malignant until proven otherwise. Perforation of the diverticular wall during biopsy risks tumor seeding into the perivesical fat with potential adverse prognostic implications.**

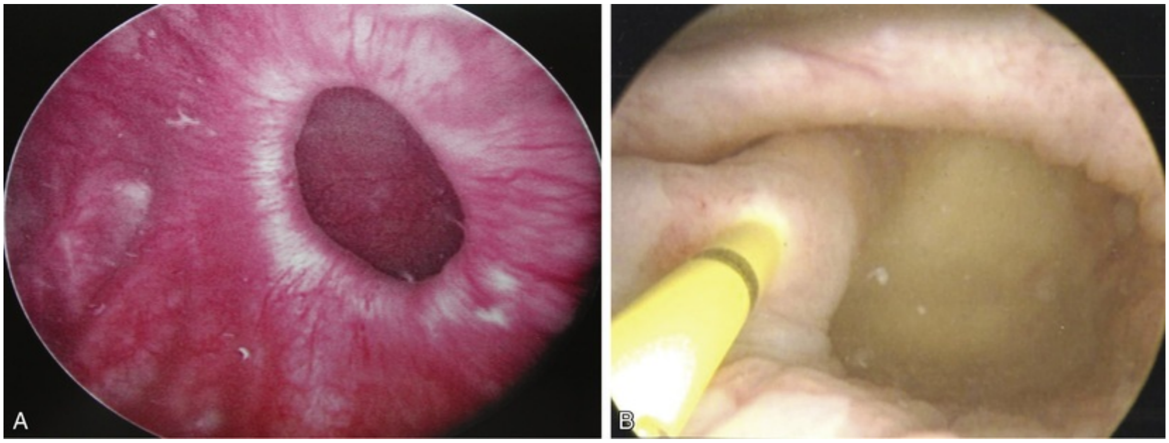

FIG. 130.8 Endoscopic views of bladder diverticula. (A) Lateral wall diverticulum in a male with bladder outlet obstruction. (B) Paraureteral diverticulum in an adult female with vesicoureteral reflux and urinary tract infections. The right ureter is intubated with a catheter.

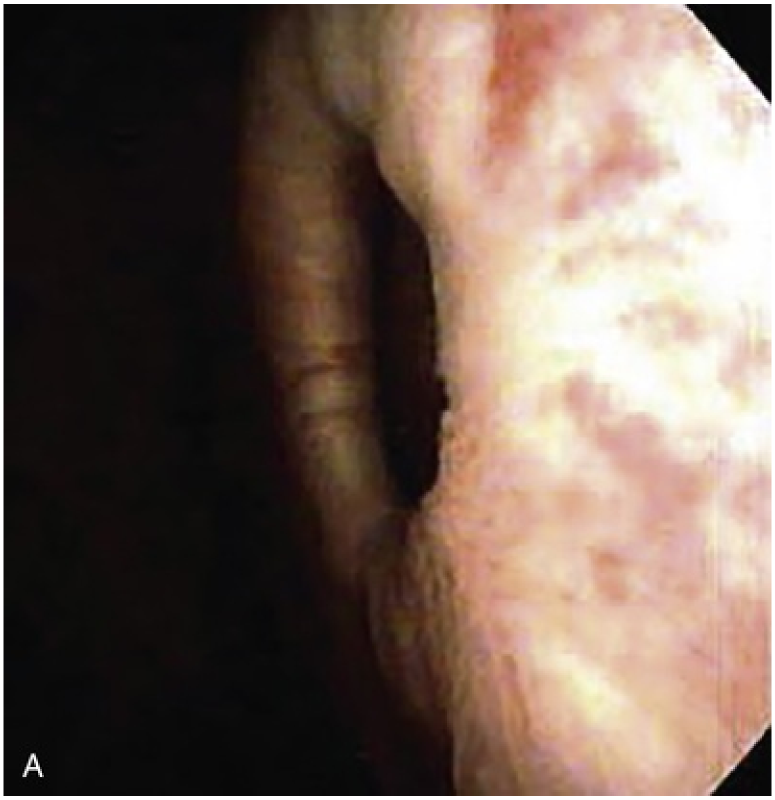

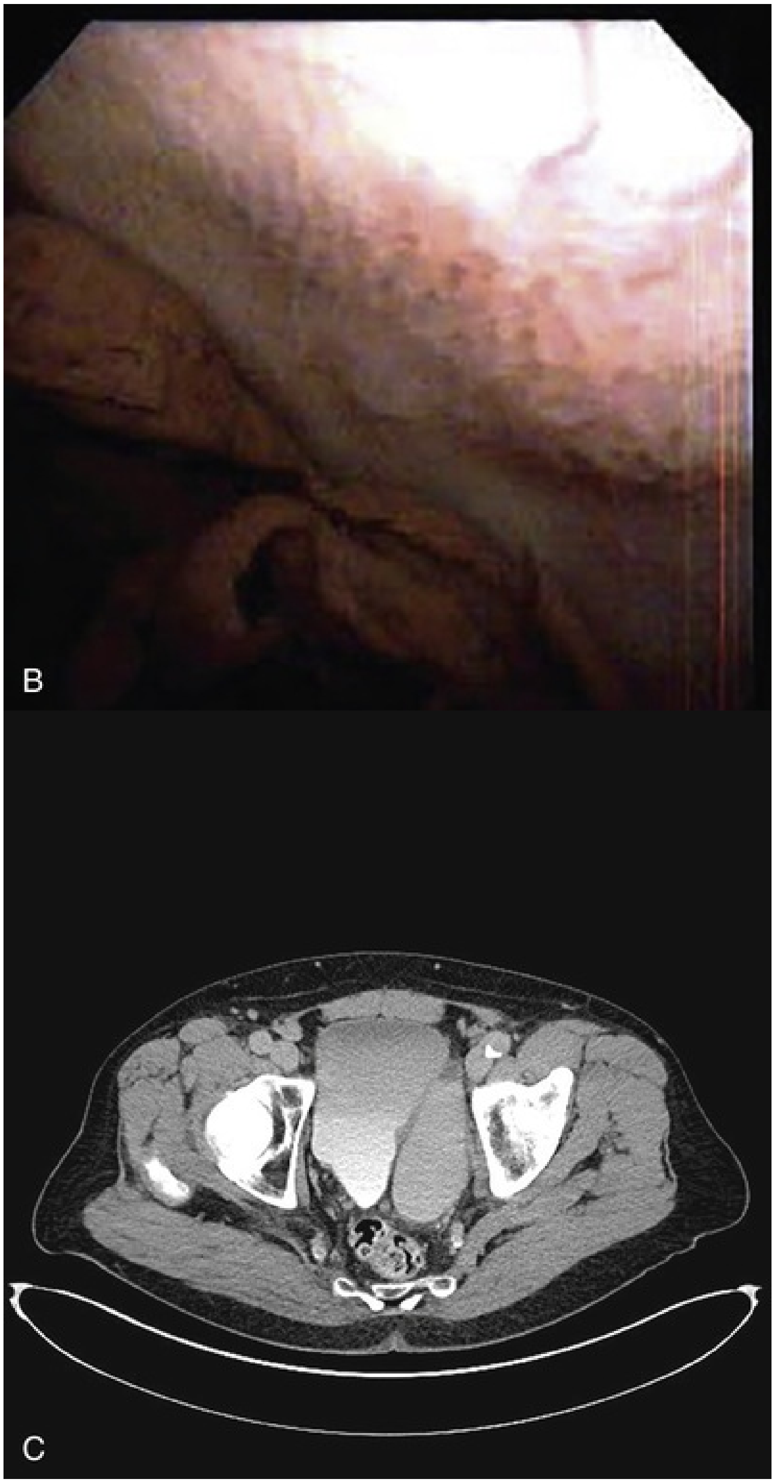

FIG. 130.9 Papillary urothelial malignancy in a bladder diverticulum. (A) Endoscopic view of the ostia of the bladder diverticulum. (B) Endoscopic view of the papillary lesion within the diverticulum. (C) Axial computed tomography scan of bladder diverticulum showing no mass.

Patients who elect nonoperative management of bladder diverticula are

usually followed closely with periodic endoscopic examinations and cytology. The natural history of untreated bladder diverticula is unknown, but the possibility of malignant transformation over time because of urinary stasis within the diverticulum should be considered.

Associated Conditions

Bladder Outlet Obstruction

Acquired bladder diverticula are commonly found to exist in the setting of bladder outlet obstruction. Common causes of bladder outlet obstruction in the male include benign and malignant disease of the prostate and urethral stricture disease. Less common causes include bladder neck hypertrophy (primary bladder neck obstruction), vesicourethral anastomotic stricture after prostatectomy, and functional obstruction as a result of neurogenic vesicourethral dysfunction (bladder neck and/or striated sphincter dyssynergia). Strong consideration should be given toward management of bladder outlet obstruction before or concomitant with treatment of the bladder diverticulum. Whether such procedures should be done concomitantly or staged is controversial (Powell and Kreder, 2009). **In some patients, especially those with small diverticula, treatment of bladder outlet obstruction alone may subsequently allow low pressure and complete emptying of the bladder diverticulum with micturition, thus reducing the potential for complications associated with these lesions and possibly avoiding the need for future operative intervention in the form of surgical diverticulectomy.**

Malignancy

Much has been written about the association of bladder diverticula and malignancy. **Historically, the risk of malignancy in bladder diverticula has been reported to be elevated. This increased risk of bladder cancer in diverticula has been attributed to urinary stasis and to chronic inflammation that is often found on pathological examination of bladder diverticulum tissue** (Idrees et al., 2013; Kelalis and McLean, 1967). Forty-five percent to 80% of bladder diverticulectomy specimens harbor inflammatory changes to the urothelium (Gerridzen and Futter, 1982; Idrees et al., 2013; Kong et al., 2013). **The overall prevalence of malignant tumors within a bladder diverticulum has been reported as ranging from 0.8% to 10%** (Baniel and

Vishna, 1997; Golijanin et al., 2003; Melekos et al., 1987; Mićić and Ilić, 1983; Montague and Boltuch, 1976). **However, it is likely that the prevalence of bladder diverticula overall is under-reported and, as such, the prevalence of tumors within diverticula is probably considerably smaller than that noted here. Nevertheless, the most common histologic type of malignancy seen within bladder diverticula is urothelial cell carcinoma in approximately 70% to 80% of cases, followed by squamous cell carcinoma in 20% to 25% of cases** (Baniel and Vishna, 1997; Golijanin et al., 2003; Mićić and Ilić, 1983; Montague and Boltuch, 1976; Redman et al., 1976; Van Arsdalen and Wein, 1992; Yu et al., 1993). Tumors in bladder diverticula occur almost exclusively in adults, with a peak occurrence between ages 65 and 75 (Ostroff et al., 1973).

In addition to the potentially increased risk of bladder cancer, **the finding of a neoplasm within a bladder diverticulum has particularly important diagnostic and therapeutic considerations because the bladder diverticulum wall lacks a well-developed muscularis propria layer,** and such tumors are at greater risk of being high grade and invasive as compared with non-diverticular bladder cancers (Kong et al., 2013). Therefore such a finding may portend a poorer prognosis because of the potential for rapid transmural involvement of invasive bladder cancer and extravesical extension. **In addition, the lack of a defined muscular wall risks early dissemination of tumor cells into an extravesical location during transurethral resection of these lesions and makes precise pathological staging difficult** (Idrees et al., 2013).

The prognosis for patients with these tumors has been historically reported as poor (Das and Amar, 1986; Faysal and Freiha, 1981; Melekos et al., 1987; Mićić and Ilić, 1983), although some reports may suggest otherwise in selected patients (Baniel and Vishna, 1997; Bourgi et al., 2016; Montague and Boltuch, 1976). The poor prognosis has been attributed to delayed diagnosis and advanced stage at presentation (Faysal and Freiha, 1981; Fellows, 1978; Mićić and Ilić, 1983; Ostroff et al., 1973). Historically, this has supported the prophylactic surgical treatment of all bladder diverticula, including asymptomatic and minimally symptomatic lesions (Kelalis and McLean, 1967). However, **more recently it has been suggested that such management is not warranted, and observation with careful follow-up and periodic endoscopic surveillance is acceptable in asymptomatic individuals without evidence of dysplastic or malignant changes** (Fellows, 1978).

Accurate identification of tumors within bladder diverticula has been demonstrated using a variety of radiographic techniques, including CT, MRI, and ultrasonography (Dondalski et al., 1993; Dragsted et al., 1985; Durfee et al., 1997; Lowe et al., 1989; Mallampati and Siegelman, 2004; Saez et al., 1985; Williams and Gooding, 1985) (see Fig. 130.5). Whether these modalities can reliably predict extravesical invasion and therefore affect staging and prognosis is not clear, although one small series suggests that certain radiographic features, including tumor length and width on CT, correlate with survival (Di Paolo et al., 2015). **It has been suggested that clinical stage at presentation is the most important prognostic factor for patients with tumors in bladder diverticula, with 5-year actuarial survival ranging from 83% ± 9% in patients with superficial disease to 45% ± 14% in those with extradiverticular disease** (Golijanin et al., 2003). One small series suggests that aggressive individualized multimodal therapy in these patients, including surgery, chemotherapy, and radiation therapy, may improve prognosis (Garzotto et al., 1996). Because pathological staging after transurethral resection is difficult and often inaccurate, some authors have suggested a very aggressive approach to these tumors. This surgical staging approach involves an open exploration and partial or radical cystectomy without a prior transurethral resection (Redman et al., 1976). Others have advocated a selective individualized approach, taking into account the clinical stage and pathological grade of the tumor (Golijanin et al., 2003). Radical cystectomy has similar outcomes for tumors within diverticula as for tumors in other locations. Hu et al. (2015) found that there was no difference in recurrence-free survival or overall survival after radical cystectomy in patients with or without urothelial carcinoma in a bladder diverticulum when stratified by stage.

Low-grade, low-stage tumors may be successfully treated with diverticulectomy alone (Baniel and Vishna, 1997; Bourgi et al., 2016; Sulaiman et al., 1998); however, it is important to recognize that the ability to reliably predict stage and grade preoperatively is limited, and therefore this approach should be undertaken only with caution in select cases, with adequate counseling and follow-up.

The role for less invasive treatment strategies of low-grade bladder tumors found in bladder diverticula is not well defined. As noted earlier, the potential risk of perforation with transurethral resection is higher with these tumors because of the lack of a defined muscularis propria layer. However, whether these patients can be safely treated with biopsy and fulguration with or without intravesical chemotherapy/immunotherapy and interval cystoscopic surveillance for low-grade tumors, is unclear.

Other Associated Conditions

The location of many bladder diverticula at the level of the ureterovesical junction may explain the high incidence of associated ipsilateral ureteral abnormalities. For a ureter found within a diverticulum, the lack of a muscular backing to the diverticulum results in a functionally shortened intramural tunnel (see Fig. 130.7). **A very high prevalence of ipsilateral vesicoureteral reflux has been noted in association with congenital bladder diverticula** (Amar, 1972; Barrett et al., 1976). Other considerations in the evaluation and management of bladder diverticula include the potential development of stones within the diverticulum, ureteral obstruction (Bellinger et al., 1985; Khan et al., 1994; Kwan and Lowe, 1992; Lebowitz et al., 1979; Sharma et al., 1997), and even the potential for the rare but life-threatening complication of perforation and/or rupture of the bladder diverticulum (Itoh and Kounami, 1994; Jorion and Michel, 1999; Keeler and Sant, 1990; Mitchell and Hamilton, 1971).

Key Points: Bladder Diverticula: Diagnosis

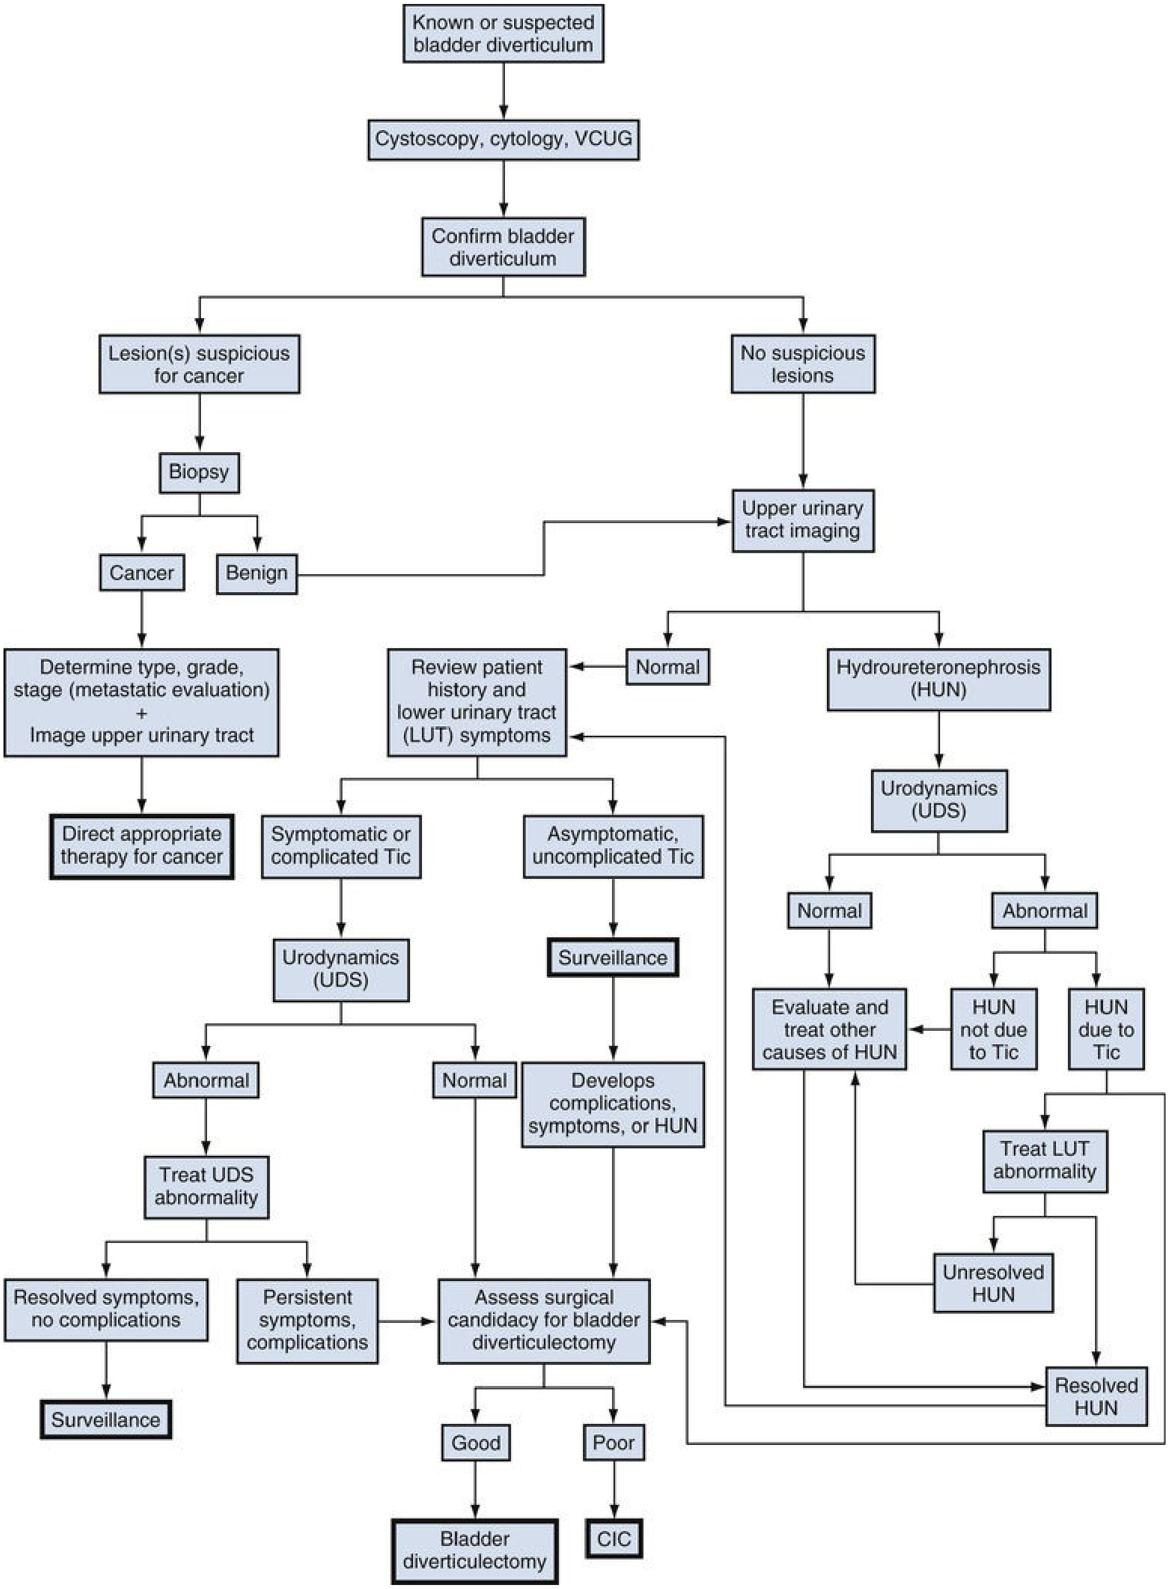
- Bladder diverticula do not contain a defined functional muscularis propria layer, and therefore larger ones generally empty poorly with micturition.
- In the adult, bladder diverticula are often associated with bladder outlet obstruction or neurogenic vesicourethral dysfunction.
- Many bladder diverticula are found in a paraureteric location.
- Bladder diverticula are most often diagnosed incidentally in the evaluation of nonspecific lower urinary tract symptoms or infection.
- Patients with bladder diverticula should be evaluated for bladder outlet obstruction, and, if this is present, it should be addressed in advance of or concomitantly with definitive treatment of the bladder diverticulum.
- Malignancy can occur within a bladder diverticulum, and consideration should be given to the possibility of early extravesical disease extension because of the lack of a defined muscularis propria.

Management

In general, if the cause of the bladder diverticulum is believed to be consistent with bladder outlet obstruction and there are no other

complicating factors, definitive treatment of the bladder outlet is indicated before formal diverticulectomy. This approach allows reassessment of the diverticulum after relief of outlet obstruction and, if bladder emptying is satisfactory and symptoms resolve, then the diverticulum may not require surgical excision. However, simultaneous open bladder diverticulectomy/open prostatectomy as well as simultaneous bladder diverticulectomy/transurethral prostatectomy can be performed (Porpiglia et al., 2004). If treatment of the obstruction is pursued initially and results in satisfactory emptying of the diverticulum postoperatively, and complicating factors such as reflux, infection, malignancy, or stones are absent, then ongoing surveillance of the diverticulum may be all that is required. Emptying of the diverticulum after relief of outlet obstruction may be assessed on VCUG, video-urodynamics, or cross-sectional imaging such as ultrasound.

Management options in the treatment of bladder diverticula include observation, endoscopic management, and surgical excision; however, there are many factors to consider during the evaluation of these lesions before deciding on appropriate therapy (Fig. 130.10).



Known or suspected bladder diverticulum
Cystoscopy, cytology, VCUG
Confirm bladder diverticulum
Lesion(s) suspicious for cancer
No suspicious lesions
Biopsy

Observation and Nonsurgical Management

Adult patients with minimal symptoms and no complicating factors may opt for observation with surveillance. These patients should be counseled regarding the potentially increased risk of malignancy and the need for periodic reassessment as well as the unpredictable course and potentially aggressive nature of malignancy if subsequently found in this setting. They should also be counseled regarding the symptoms and signs that indicate progression, including increasing lower urinary tract symptoms, hematuria, and UTI. **The optimal schedule and type of surveillance for those individuals choosing observation is not well defined but consists of a periodic reassessment of symptoms, urine studies (including cytology), and endoscopic examination of the lower urinary tract** (Yu et al., 1993).

Patients who have poor bladder emptying after relief of obstruction and remain symptomatic, or those who are unable or unwilling to undergo surgical excision of the bladder diverticulum, may be effectively treated with clean intermittent catheterization (CIC) or an indwelling catheter. In this setting, and in the absence of future complicating factors, ongoing CIC and periodic surveillance of the bladder diverticulum may be acceptable.

Indications for bladder diverticulectomy in children are similar to those in adults. However, in children with multiple bladder diverticula associated with a chromosomal syndrome, observation and medical management are usually preferred because of the inherent connective tissue disorders found in these patients, which impair postoperative wound healing, increase perioperative surgical risk, and predispose to recurrence (Psutka and Cendron, 2013).

Indications for Intervention

Many patients with incidentally found congenital or acquired bladder diverticula are managed expectantly and with periodic surveillance. Bladder diverticula can vary tremendously in size and, in some instances, are larger than the bladder. The size of the diverticulum does not appear to correlate with symptoms or complications and therefore cannot be used as an absolute indication to proceed with surgery. **Bladder diverticulectomy is indicated for**

the treatment of lower urinary tract symptoms related to the diverticulum that are not otherwise responsive to medical therapy, or for the major complications directly related to it: persistent symptoms, chronic relapsing UTI, stones within the diverticulum, carcinoma or premalignant change, and upper urinary tract deterioration as a result of obstruction or reflux. Symptoms or complications related to bladder diverticula are most often due to poor emptying of the diverticulum and urinary stasis. Therefore excision of the diverticula would be expected to improve emptying of the lower urinary tract, provided that the primary problem that resulted in the formation of the bladder diverticulum (i.e., obstruction) has been adequately addressed.

Excision of bladder diverticula is most commonly elective. The relative merits of surgical excision versus surveillance should be carefully considered and discussed with each patient individually. The patient should be in relatively good health and be a reasonable surgical risk before considering the procedure. Preoperative medical status should be assessed and reversible risk factors (e.g., nutritional, renal, cardiac, pulmonary) corrected and/or optimized. Preoperative UTI should be treated. Patients who have prohibitive surgical risks because of concurrent medical illness or other factors should not undergo surgical excision but may be candidates for CIC or endoscopic treatment.

Endoscopic Management

Endoscopic management of bladder diverticulum may be considered in patients who are aged or somewhat debilitated, those who are not good candidates for an open operative approach, or those undergoing transurethral resection of the prostate in whom there exists an associated poorly draining diverticulum (Orandi, 1977; Vitale and Woodside, 1979).

Transurethral resection of the diverticular neck has been reported to be successful in select cases (Vitale and Woodside, 1979). This technique is usually performed with a standard resectoscope. The neck of the diverticulum is incised using the resectoscope loop or Collins knife. Incisions are carried down to the muscular fibers of the bladder at the level of the ostium of the diverticulum. Circumferential resection of the entire neck may be performed. When successful, this procedure enlarges the neck of the diverticulum, disrupting the narrow sphincteric-like properties of its connection to the bladder lumen and thereby permitting improved emptying of the diverticulum during micturition. Although generally safe and well tolerated, this technique has resulted in urinary retention because of a reversal of flow during micturition and “venting” of the bladder contents into the diverticulum postoperatively (Schulze and Hald, 1983). This technique has been reported to be less successful in those individuals with large diverticula (Orandi, 1977; Vitale and Woodside, 1979). **Transurethral resection of the diverticular neck may be combined with fulguration of the entire urothelial lining of the diverticulum** (Adachi et al., 1991a,b; Clayman et al., 1984; Yamaguchi et al., 1992). Fulguration of the lining of the diverticulum should result in obliteration of the diverticulum or a considerable reduction in its size.

Operative Excision

Operative excision may be performed through an open, laparoscopic, or robotic approach with or without concomitant treatment of associated bladder outlet obstruction.

Key Points: Bladder Diverticula: Management

- Bladder diverticulectomy is not indicated in all cases. Surgical treatment should be reserved for the treatment of symptoms related to the diverticulum, chronic relapsing UTI stones within the diverticulum, carcinoma or premalignant change, and upper urinary tract deterioration as a result of obstruction or reflux.
- Surgical diverticulectomy can be performed with a variety of approaches, including minimally invasive techniques, and treatment of concomitant bladder outlet obstruction, if present, should be considered.

Female Urethral Diverticula

Urethral diverticula (UD) in female patients are variably sized, urine-filled periurethral cystic structures adjacent to the urethra within the confines of the pelvic fascia, connected to the urethra via an ostium. Such lesions represent some of the most challenging diagnostic and reconstructive problems in female urology. UD are notable for a bewildering array of clinical presentations ranging from completely asymptomatic, incidentally noted lesions on physical examination or imaging, to very debilitating, painful vaginal masses associated with incontinence, stones, severe dyspareunia, and/or tumors. Anatomic variations between patients and in the location, size, and complexity of these lesions ensure that each case is unique.

Although described as early as the 19th century (Hey, 1805), the modern era of female UD began in the 1950s with the advent of positive-pressure urethrography (PPU) by Davis and Cian (1956). Over the next several years, there was a dramatic increase in number of cases of UD reported in the literature. A published series of 121 cases by Davis and TeLinde (1958) approximately doubled the number of cases reported during the previous 60 years. Development of adjuvant imaging techniques such as ultrasonography and surface coil/endoluminal MRI have contributed greatly to further understanding of UD (Fig. 130.11).

Anatomy of the Female Urethra

The normal female urethra is a musculofascial tube approximately 3 to 4 cm in length, extending from the bladder neck to the external urethral meatus, suspended from the pelvic sidewall and pelvic fascia (tendinous arc of the obturator muscle) by a sheet of connective tissue known as the urethropelvic ligament. The urethropelvic ligament is composed of two layers of fused pelvic fascia that extend toward the pelvic sidewall bilaterally (Fig. 130.12). This structure can be considered to have an abdominal side (the endopelvic fascia) and a vaginal side (the periurethral fascia). **Within and between these two leaves of fascia lie the urethra and the location of most UD.**

FIG. 130.12 Schematic diagram of the anatomy of the mid-urethra in the coronal plane.

The urethral lumen is lined by a urothelial layer proximally and a nonkeratinized stratified squamous cell type distally. The urethra may be conceptualized as a rich, vascular, spongy cylinder surrounded by an envelope consisting of smooth and skeletal muscle and fibroelastic tissue (Young and Wahle, 1996). **Within the thick, vascular lamina propria/submucosal layer are the periurethral glands** (Fig. 130.13). These tubuloalveolar glands exist over the entire length of the urethra posterolaterally; however, **they are most prominent over the distal two-thirds,** with the majority of the glands draining into the distal one-third of the urethra. **It is from pathological processes involving the periurethral glands that most acquired female UD are thought**

to originate. The Skene glands are the largest and most distal of these glands and are sometimes called the *paraurethral glands*. These paraurethral glands drain outside the urethral lumen, lateral to the urethral meatus.

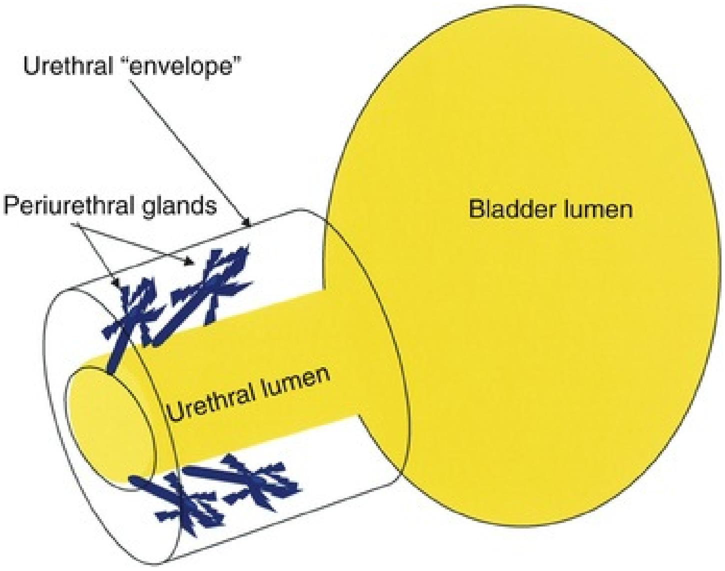

FIG. 130.13 Periurethral glands are located within the submucosa of the urethra deep to the muscular envelope, draining distally but arborizing proximally.

The urethra has several muscular layers: an internal longitudinal smooth muscle layer, an outer circular smooth muscle layer, and a skeletal muscle layer. The skeletal muscle component spans much of the length of the urethra but is more prominent in the middle third. It has a U-shaped configuration, deficient dorsally. Ventral to the urethra, but separated from it by the periurethral fascia, lies the anterior vaginal wall (see Fig. 130.12). **The location and competence of the urethral sphincters have important implications when considering surgical repair of UD because of the anatomic overlap of these two entities.**

Arterial inflow to the urethra derives from two sources. **The proximal urethra has a blood supply similar to the adjacent bladder, whereas the distal urethra derives its blood supply from the terminal branches of the inferior vesical artery through the vaginal artery that runs along the superior lateral aspect of the vagina** (Hinman, 1993). **Lymphatic drainage of the female urethra is to the external and internal iliac nodes from the proximal urethra and to the superficial and deep inguinal lymph nodes from the distal urethra. Innervation to the female urethra is from the**

pudendal nerve (S2 to S4), and afferents from the urethra travel through the pelvic splanchnic nerves.

Urethral Diverticula

Pathophysiology and Etiology

As conceptualized by Young and Wahle (1996), UD represent a cavity dissecting within the confines of the fascia of the urethropelvic ligament. This defect is often an isolated cystlike appendage with a single discrete connection to the urethral lumen known as the neck, or ostium (Fig. 130.14). **However, complicated anatomic patterns may exist, and in certain cases the UD may extend partially (saddlebag UD) around the urethra, anterior to the urethra** (Vakili et al., 2003)**, or circumferentially around the entire urethra** (Rovner and Wein, 2003; Fig. 130.15).

The exact origin of UD is still unproven. A major debate in the early part of the 20th century focused on whether UD were congenital or acquired lesions (Gilbert and Rivera Cintron, 1954; Johnson, 1938; Pinkerton, 1963). Although this condition exists in children, the diagnosis may represent a different clinical entity from adult female UD. Scattered reports of congenital UD in female infants have been described (Glassman et al., 1975). Marshall (1981) reported five cases of UD in young females, of whom three experienced spontaneous regression. Congenital anterior UD is a well-described entity in boys (Kaneti et al., 1984; Kirks and Grossman, 1981; Lau and Ong, 1981), but this is considered to be an entirely different clinical entity from UD in the female. Congenital Skene gland cysts have been reported (Kimbrough and Vaughan Jr., 1977; Lee and Kim, 1992) but are considered extremely rare. Diverticula in the pediatric population have been attributed to a number of congenital anomalies, including an ectopic ureter draining into a Gartner duct cyst and a forme fruste of urethral duplication (Boyd and Raz, 1993; Silk and Lebowitz, 1969; Vanhoutte, 1970). **The vast majority of UD, however, are classified as acquired and are diagnosed in adult females.** In two large series of UD, there were no patients reported who were younger than 10 years of age (Davis et al., 1958, 1970), arguing against a congenital cause for these lesions. A congenital defect in patients that results in or represents a precursor to UD, which then only becomes symptomatic later in life, may exist; however, this is still unproven.

There are multiple theories regarding the formation of acquired UD. For many years, acquired UD were believed to be most likely the result of trauma from vaginal childbirth (McNally, 1935). It was postulated that mechanical trauma during vaginal delivery resulted in herniation of the urethral mucosa through the muscular layers of the urethra with the subsequent development of a UD. However, up to 20% to 30% of patients in some UD series are nulliparous (Ganabathi et al., 1994; Lee, 1984), which may significantly discount parity as a risk factor. Trauma with forceps delivery, however, has been reported to cause UD (Kłyszejko et al., 1985), and the radiographic appearance of periurethral injectable agents, including collagen (Bridges et al., 2005; Clemens and Bushman, 2001) and other injectable agents (Castillo-Vico et al., 2007; Gaines et al., 2017), can simulate a UD.

The periurethral glands are thought to be the probable site of origin of acquired UD (Young and Wahle, 1996). Huffman's anatomic work (1948) with wax models of the female urethra was critical to the early theories regarding the pathophysiology of UD and the involvement of the periurethral glands. By reviewing 10-μm transverse sections, he refuted earlier anatomic descriptions of the glandular anatomy of the female. He characterized the periurethral glands as located primarily dorsolateral to the urethra, arborizing proximally along the urethra, and yet draining into ducts located in the distal one-third of the urethra (see Fig. 130.13). Furthermore, he noted that periductal and interductal inflammation was found commonly. **In support of these observations and an infectious (acquired) cause of UD, in more than 90% of UD cases the ostium is located posterolaterally in the mid- or distal urethra, which corresponds to the anatomic location of the periurethral glands** (Lang and Davis, 1959; Mackinnon et al., 1959).

Although there are probably other unknown factors that may facilitate the initiation, formation, or propagation of UD, infection of the periurethral glands seems to the most generally accepted common etiologic factor in most cases. Peters and Vaughan (1976) found a strong association with concurrent or previous infection with *Neisseria gonorrhoeae* and UD. However, the initial infection and, especially, subsequent reinfections may originate from a variety of sources, including *Escherichia coli* and other coliform bacteria as well as vaginal flora. **Nevertheless, UD have been attributed historically to recurrent infection of the periurethral glands, with obstruction, suburethral abscess formation, and subsequent rupture of these infected glands into the urethral lumen.** Continual filling and pooling of urine in the resultant cavity may lead to stasis, recurrent infection, and eventual epithelialization of the cavity, forming a permanent UD. This concept was first popularized by Routh (1890) more than a century ago and has now become the most widely accepted theory regarding the formation of female UD. **Reinfection, inflammation, and recurrent obstruction of the neck of the cavity are theorized to result in patient symptoms and enlargement of the diverticulum.** Daneshgari et al. (1999) have reported noncommunicating UD diagnosed by MRI. Whether this lesion represents a forme fruste of UD or simply a UD with an obstructed ostium is unclear.

Young and Wahle (1996) have formulated a modern hypothesis regarding the pathogenesis of UD through extensive clinical experience with this entity, including the diagnosis, imaging, and surgical repair of UD. **These authors have proposed that acquired UD results from infection and obstruction of the periurethral glands.** These glands are normally found in the submucosal layer of the spongy tissue of the distal two-thirds of the urethra. **Repeated infection and abscess formation in these obstructed glands eventually result in enlargement and expansion.** Initially the expanding mass displaces the spongy tissue of the urethral wall and then enlarges to disrupt the muscular envelope of the urethra. This results in herniation into the periurethral fascia. The enlarging cavity can then expand and dissect within the leaves of the periurethral fascia and urethropelvic ligament. **This expansion occurs most**

commonly ventrally, resulting in the classic anterior vaginal wall mass palpated on physical examination in some patients with UD. However, these may also expand laterally, or even dorsally, about the urethra. **Eventually, the abscess cavity ruptures into the urethral lumen, resulting in the communication between the UD and the urethral lumen.**

This proposed pathophysiology appears to adequately explain the anatomic location and configuration of many UD and is supported by the work of Huffman noted previously. However, it is not without critics. Some have argued that UD represent one form in the continuum of periurethral cysts (Tsivian et al., 2009). In addition, about one-third of UD occur in the proximal portion of the urethra (Thomas et al., 2008), which is not consistent with the location of the majority of the drainage ducts for the periurethral glands. Finally, if this proposed pathophysiology were true, the finding of periurethral abscesses as a result of infection and enlargement of the periurethral glands should be at least as common as UD, but such lesions are indeed rarely seen clinically.

Prevalence

Moore (1952) **stated that UD as an entity is "found in direct proportion to the avidity with which it is sought."** Although it is not considered a rare lesion today, less than 100 cases of UD were reported in the literature before 1950. With the development of sophisticated imaging techniques, including PPU in the 1950s, the diagnosis of UD became increasingly common.

The true prevalence of female UD, however, is not known; it is reported to occur in up to 1% to 6% of adult females in some series. Determining the true prevalence of UD would require appropriate screening and imaging of a large number of symptomatic and asymptomatic adult female subjects in a primary care setting, which has not been done. Bruning (1959) found UD in 3 of 500 female autopsy specimens. In 1967 Andersen reported the results of PPU done for 300 women with cervical cancer but without lower urinary tract symptoms and found UD in 3%. Aldridge et al. (1978) reported a prevalence of UD of 1.4% in women with incontinence and related symptoms. Stewart et al. (1981) found UD in 16 of 40 highly symptomatic females investigated with PPU. Endorectal coil MRI was performed on 140 consecutive female patients with lower urinary tract symptoms, and the incidence of UD was approximately 10% (Lorenzo et al., 2003). However, this represented a series of *symptomatic* females at a tertiary referral center and therefore probably is not reflective of the general population. Burrows et al. (2005) reviewed US hospital and ambulatory surgery databases and concluded that the rate of urethral diverticulectomy surgery from 1994 to 1996 was approximately 6.7 per 1 million females. However, this is well below the historical prevalence figures cited previously. A population-based study of women in Olmstead County, Minnesota, by El-Nashar et al. (2014) found that the incidence of UD is less than 0.02% per year. Further complicating an accurate assessment of the epidemiology of UD is that the condition can be asymptomatic and is often misdiagnosed or overlooked. A population-based study of women in Olmstead County, Minnesota, by El-Nashar et al. (2014) found that the incidence of UD is less than 0.02% per year.

Some series have suggested a racial predilection, with African-Americans being as much as six times as likely to develop UD as their Caucasian counterparts (Davis et al., 1970). This distribution was historically believed to be attributed to an urban bias because most of the clinical series of these cases were reported from academic medical centers in large cities. However, a recent retrospective series from the Cleveland Clinic revealed that approximately two-thirds of urethral diverticulectomies performed at that institution over a 26-year period were in Caucasians. Nevertheless, inpatient surgery for UD in the United States occurred threefold more commonly in African-Americans than in whites from 1979 to 1997 (Burrows et al., 2005).

Diverticular Anatomy and Histology

The interior surface of UD may be urothelial, squamous, columnar, or cuboidal epithelium, or mixed (Tsivian et al., 2009)**. In some cases, the epithelium is absent and the wall of the UD consists of only fibrous tissue. Two-thirds of resected UD demonstrate inflammatory changes** (Thomas et al., 2008).

Most UD demonstrate benign histopathology, but premalignant and malignant changes can be seen. Approximately 10% of urethral diverticulectomy specimens may demonstrate significant histopathologic abnormalities, including metaplasia, dysplasia, or frank carcinoma, which require long-term follow-up or additional therapy (Thomas et al., 2008)**. Fewer than 100 cases of carcinoma within UD have been reported in the English-language literature** (Rajan et al., 1993)**. The most common malignant pathology in UD is adenocarcinoma, followed by urothelial cell and squamous cell carcinomas** (Rajan et al., 1993; Thomas et al., 2008)**. This**

is in direct contrast to primary urethral carcinoma, in which the primary histologic type is squamous cell carcinoma. Some authors have suggested that UD is associated with the development of urethral adenocarcinoma in the female (Oliva and Young, 1996). If this is true, then observational management or nonexcisional therapy of UD, such as marsupialization or endoscopic incision, should always be combined with a biopsy to rule out malignancy (McLoughlin, 1975). **There is no consensus on proper treatment in these cases of malignancy associated with UD, and recurrence rates are high with local treatment alone** (Rajan et al., 1993). The incidental finding of malignancy in these cases can be particularly troubling when found intraoperatively, or even more disturbing on the postoperative pathology report. Although it is interesting to speculate, **it has not been conclusively demonstrated that any particular preoperative imaging modality, such as ultrasonography or MRI** (Chung et al., 2010), **can reliably and prospectively diagnose a small malignancy arising in a UD.** In consideration of curative therapy, it is unclear whether extensive surgery, including cystourethrectomy with or without adjuvant external beam radiotherapy, is superior to local excision followed by radiotherapy (Patanaphan et al., 1983).

Multiple benign lesions, including nephrogenic adenoma and endometriosis, have been described within UD (Laudano et al., 2014; Paik and Lee, 1997; Palagiri, 1978; Peterson and Matsumoto, 1978; Piazza et al., 1987). Pathologically, nephrogenic adenoma can be difficult to differentiate from adenocarcinoma (Laudano et al., 2014).

Calculi within UD are not uncommon and may be diagnosed in 4% to 10% of cases (Ginesin et al., 1988; Romanzi et al., 2000; Ward et al., 1967) and are most likely caused by urinary stasis and/or infection (Fig. 130.16). They may be suspected by physical examination findings or noted incidentally on imaging evaluation. **The presence of a stone will not significantly alter the evaluation or surgical approach and can be considered an incidental finding.** The stone is removed with the UD specimen at the time of surgery.

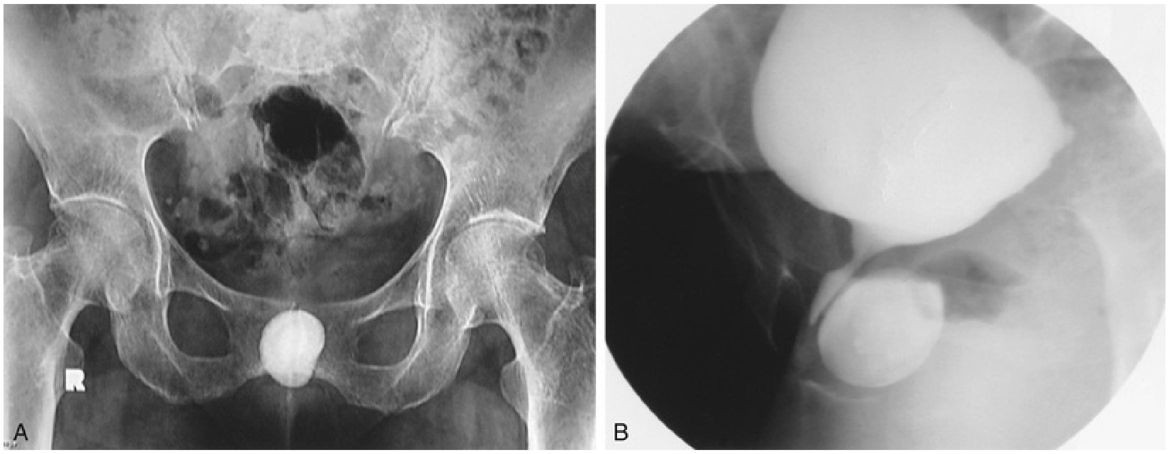

FIG. 130.16 Calculi within a urethral diverticulum. (A) Scout film shows a calcified density overlying the symphysis pubis. (B) Voiding image from a voiding cystourethrogram demonstrates that the density seen on the scout film represents a stone within a urethral diverticulum.

UD are found within the periurethral fascia bordered by the anterior vaginal wall ventrally. **The size of the lesion may vary from only a few millimeters to several centimeters.** In addition, the size may vary over time as a result of inflammation, intermittent obstruction of the ostium, and subsequent drainage into the urethral lumen. In the sagittal plane, UD are most often located and centered at the level of the middle third of the urethra, with the luminal connection, or ostium, located posterolaterally. They may extend distally along the vaginal wall almost to the urethral meatus, or proximally up to and beyond the bladder neck underneath the trigone of the bladder (Fig. 130.17). A bewildering array of configurations can be noted on imaging and at surgical exploration (Table 130.1). In the axial plane, the UD cavity may extend laterally along the urethral wall and, in some cases, around to the dorsal side of the urethra or may wrap circumferentially around the entire urethra. UD may be bilobed (dumbbell shaped), extending across the midline in a so-called saddlebag configuration (see Fig. 130.15). Multiple loculations are not uncommon, and approximately 6% of patients have multiple UD at presentation (Thomas et al., 2008). Varying degrees of sphincteric compromise may exist because of the location of diverticulum relative to the proximal and distal urinary sphincter mechanisms, or sphincteric compromise may coexist with UD as a result of other factors. This is important to note when considering surgical repair, as discussed later.

Presentation

The majority of patients with UD are seen initially between the third and seventh decades of life (Ganabathi et al., 1994; Ginsburg and Genadry, 1983; Johnson, 1938; Moore, 1952; Pathak and House, 1970). The presenting symptoms and signs in patients with UD are protean (Box 130.1). **The classic presentation of UD has been described historically as the "three Ds"—dysuria, dyspareunia, and dribbling (postvoid)—but this presentation is**

only infrequently seen, with recent series showing that only 5% of contemporary cases have all three (Baradaran et al., 2016). Such a designation is of historical interest only because it was coined in the period before extensive radiologic imaging was available (Lee and Fynes, 2005). However, individually or collectively, these symptoms are neither sensitive nor specific for UD. **Although presentation is highly variable, the most common symptoms are irritative lower urinary tract symptoms (e.g., frequency, urgency), pain, and infection** (Baradaran et al., 2016; Davis et al., 1958, 1970; Leach et al., 1986; Nickles et al., 2014; Peters III and Vaughan Jr, 1976). **Dyspareunia will be noted by 12% to 24% of patients** (Davis et al., 1958, 1970). **Approximately 5% to 32% of patients will complain of postvoid dribbling** (Davis et al., 1970; Ganabathi et al., 1994), and one-third will have associated incontinence (Ganabathi et al., 1994). **Recurrent cystitis or UTI is also a frequent presentation, seen in one-third of subjects** (Davis et al., 1970; Ganabathi et al., 1994), **probably as a result of urinary stasis in the UD. Multiple bouts of recurrent cystitis should alert the clinician to the possibility of a UD. Other complaints include pain, a vaginal mass, hematuria, vaginal discharge, obstructive symptoms, or urinary retention.** Patients may complain of a tender or nontender anterior vaginal wall mass, which upon gentle compression may reveal retained urine or purulent discharge per the urethral meatus. Although spontaneous rupture of these lesions is extremely rare, urethrovaginal fistula may result under these circumstances (Nielsen et al., 1987). **Notably, up to 10% to 20% of patients diagnosed with UD may be completely asymptomatic, having the lesions diagnosed incidentally on imaging or physical examination** (Baradaran et al., 2016).

Box 130.1

Signs and Symptoms of Urethral Diverticula

Symptoms

Vaginal or pelvic mass
Pelvic pain
Urethral pain
Dysuria
Urinary frequency

- Postvoid dribbling
- Dyspareunia
- Urinary urgency
- Incontinence
- Urinary hesitancy
- Vaginal or urethral discharge
- Double voiding
- Sense of incomplete emptying

Signs

- Recurrent urinary tract infection
- Hematuria
- Vaginal or perineal tenderness
- Urinary retention
- Vaginal mass
- Urethral discharge with stripping of anterior vaginal wall

The size and complexity of the UD do not correlate with symptoms (Nickles et al., 2014). In some cases, very large UD may result in minimal symptoms, and, conversely, some UD that are nonpalpable may result in considerable patient discomfort and distress. Finally, symptoms may wax and wane and even resolve for long periods of time. The reasons for these exacerbations and remissions are poorly understood but may be related to periodic and repeated episodes of infection and inflammation.

Because many of the symptoms associated with UD are nonspecific, patients may often be misdiagnosed and treated for years for a number of unrelated conditions before the diagnosis of UD is made. This may include therapies for interstitial cystitis, recurrent cystitis, vulvodynia, endometriosis, and vulvovestibulitis. In one series of 46 consecutively examined women eventually diagnosed with UD, the mean interval from onset of symptoms to diagnosis was 5.2 years (Romanzi et al., 2000). In this series, women consulted with an average of nine physicians before the definitive diagnosis being made, despite the fact that 52% of women had a palpable mass on examination. This underscores the importance of a baseline level of suspicion and a thorough pelvic examination in female patients complaining of lower urinary tract symptoms or other symptoms that may be associated with UD.

UD has also been reported to present during pregnancy. Moran et al. (1998) reported four cases of UD diagnosed during pregnancy. Conservative treatment included antibiotics and aspiration or incision and drainage. Two women delivered vaginally and the other two delivered by cesarean section for unrelated reasons. In one patient, drainage was performed during labor to facilitate delivery. Three of the four women had definitive repair performed after delivery. It is not known if pregnancy is associated with formation of UD, although patients may be more likely to become symptomatic during this period. Usually, conservative management with antibiotics may be desirable until after delivery to avoid precipitating premature labor, although successful surgical treatment during pregnancy has been reported (Wittich, 1997). Transvaginal aspiration of symptomatic lesions also can be considered.

Evaluation and Diagnosis

The diagnosis of UD can be made with a combination of a thorough history, physical examination, appropriate urine studies (including urine culture and analysis), endoscopic examination of the bladder and urethra, and selected radiologic imaging. A urodynamic study may also be helpful in completing the evaluation in selected cases.

History and Physical Examination

A thorough history is essential in patients with a diagnosis of UD as well as those without an established diagnosis. Although the presenting symptoms and signs are nonspecific for UD, a thorough accounting of lower urinary tract symptoms, signs (e.g., hematuria), prior diagnostic studies, and response to therapy is critical. Such an approach will permit appropriate counseling regarding improvement or resolution of symptoms in those individuals with a diagnosis of UD and may suggest such a diagnosis in those with diagnostic dilemmas. Important historical data include prior pelvic surgery, especially incontinence procedures; bulking agents may appear as UD on imaging (Gaines et al., 2017; Kumar et al., 2011); and prior sling surgery may present difficulties in accessing and surgically repairing the UD. The presence or absence of urinary incontinence and pad usage, as well as the type of incontinence (e.g., urge vs. stress vs. postvoid dribbling) should be recorded. Sexual function and dyspareunia should be documented as well because vaginal reconstructive surgery may have adverse (or favorable) effects on these individuals’ symptoms.

During physical examination, the anterior vaginal wall should be carefully palpated for masses and tenderness. The location, size, and consistency of any suspected UD should be recorded. **Most UD are located ventrally over the middle and proximal portions of the urethra, corresponding to the area of the anterior vaginal wall 1 to 3 cm inside the introitus** (Fig. 130.18). More distal lesions near the urethral meatus or those distorting the urethral meatus are likely Skene gland cysts or abscesses. Only about one-third of UD are seen initially with a tender anterior vaginal wall mass (Ganabathi et al., 1994). **However, UD may also be located anterior to the urethra or extend partially or completely around the urethral lumen. UD may also extend proximally toward the bladder neck.** These UD may produce distortion of the bladder outlet and trigone of the bladder on cystoscopy or on radiographic imaging. Special care should be taken during surgical excision and reconstruction in such cases because of concerns for intraoperative bladder and ureteral injury, as well as the potential development of postoperative voiding dysfunction and urinary incontinence.

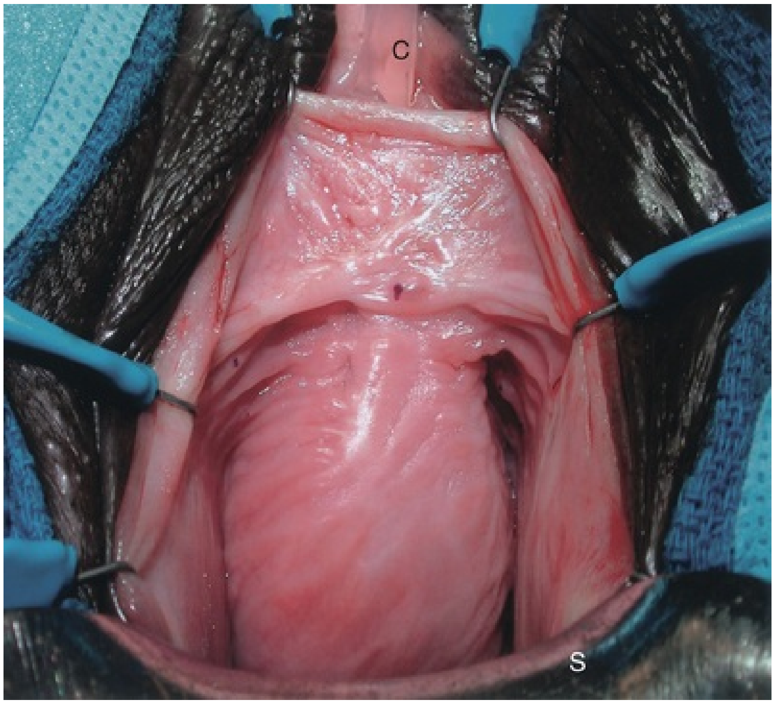

FIG. 130.18 Large anterior vaginal wall mass. The urethral catheter *(C)* is seen superiorly, and a weighted vaginal speculum *(S)* is seen inferiorly. Scott retractor hooks are seen exposing the anterior vaginal wall in this intraoperative photograph.

Distal vaginal masses or perimeatal masses may represent other lesions, including abnormalities of Skene glands (see later discussion). The differentiation between these lesions sometimes cannot be made on the basis of a physical examination alone and may require additional radiologic imaging. **A particularly hard anterior vaginal wall mass may indicate a calculus or malignancy within the UD and mandates further investigation. During physical examination, the urethra may be gently "stripped" or "milked" distally in an attempt to express purulent material or urine from within the UD cavity.** Although often described for the evaluation of UD, this maneuver is not successful in producing the characteristic discharge per urethral meatus in the majority of patients (Leach and Bavendam, 1987).

The vaginal walls are assessed for atrophy, rugation, and elasticity. Poorly estrogenized, atrophic tissues are important to note if surgery is being considered for definitive treatment. These tissues are mobilized intraoperatively and may be used for flaps during excision and reconstruction. Topical estrogens may be administered preoperatively in such cases to improve the quality of these tissues for possible reconstruction intraoperatively. The distal vagina and vaginal introitus are also assessed for capacity. These factors may have an impact on surgical planning because a narrow introitus can make surgical exposure difficult and may mandate an episiotomy or other measures. Finally, during physical examination a provocative maneuver to elicit stress incontinence should be performed, as well as an assessment of the presence or absence of any vaginal prolapse.

Urine Studies

Urine analysis and culture should be performed. The most common organism isolated in patients with UD is *E. coli*. However, other gram-negative enteric flora, as well as *N. gonorrhoeae*, *Chlamydia*, streptococci, and staphylococci, are often present (Davis et al., 1958; Hoffman and Adams, 1965). A sterile urine culture does not exclude infection, because these patients are often on antibiotic therapy at presentation. In patients with irritative symptoms or in whom a malignancy is suspected, urine cytology can be performed.

Cystourethroscopy

Cystourethroscopy is performed in an attempt to visualize the UD ostium as well as to evaluate for other causes for the patient's lower urinary tract

symptoms. A flexible fiberoptic cystoscope or specially designed rigid female cystoscope can be extremely helpful in evaluating the female urethra. The short beak of the rigid female cystoscope and the lack of a beak on a flexible cystoscope maintain the discharge of the irrigation solution immediately adjacent to the lens and thus aid in distention of the relatively short (as compared with the male) urethra, permitting improved luminal visualization when attempting to locate the ostium of the UD. It may also be advantageous to compress the bladder neck while an assistant simultaneously applies pressure to the diverticular sac with a finger. Luminal discharge of purulent material can often be seen with this maneuver or with simple digital compression of the UD during urethroscopy. **The UD ostium is most often located posterolaterally at the 4 and 8 o'clock positions at level of the mid-urethra but can be very difficult to identify in some patients** (Fig. 130.19). The success in identifying a diverticular ostium on cystourethroscopy is highly variable and is reported to range from 15% to 89% (Davis et al., 1970; Ganabathi et al., 1994; Leach and Bavendam, 1987). As a note of caution, patients with UD are often highly symptomatic, and endoscopic examination can be very difficult to initiate or complete without anesthesia. Notably, a positive examination may help in surgical planning; however, the failure to locate an ostium on cystourethroscopy should not influence the decision to proceed with further investigations or surgical repair.

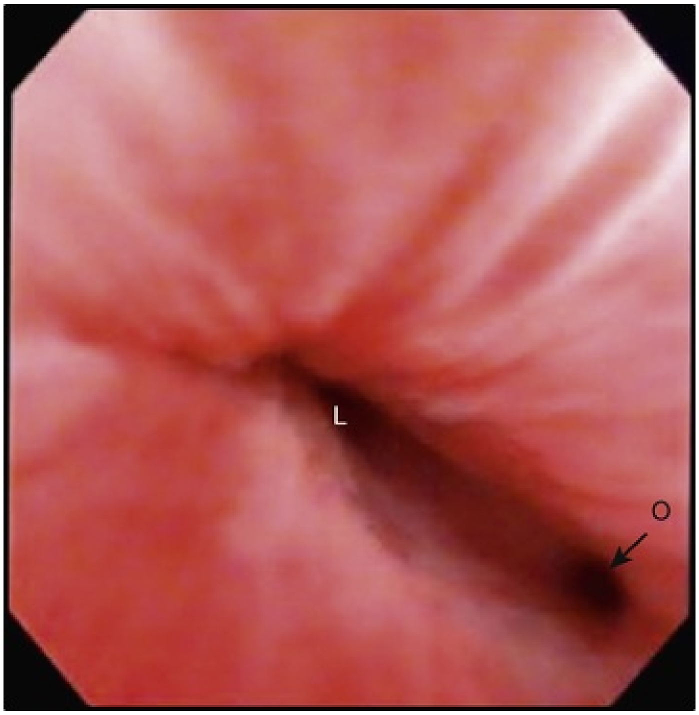

FIG. 130.19 Cystoscopic view of the ostium *(O)* of a urethral diverticulum, which is often difficult to visualize endoscopically. *L,* Lumen of the urethra.

Urodynamics

For patients with UD and urinary incontinence or significant voiding dysfunction, a urodynamic study may be helpful in accurately characterizing these symptoms (Bhatia et al., 1981; Reid et al., 1986; Summitt and Stovall, 1992). Urodynamics may document the presence or absence of stress urinary incontinence (SUI) before repair. **Approximately one-third of women with UD are seen initially with symptoms of urinary incontinence, and up to 50% of women with UD demonstrate SUI on urodynamic evaluation** (Bass and Leach, 1991; Ganabathi et al., 1994). A video-urodynamic study is optimal because it combines a VCUG and a urodynamic study, thus consolidating the diagnostic evaluation and decreasing the number of required urethral catheterizations during the patient's clinical workup (Greiman et al., 2018).

Urethral pressure profilometry has also been used by some authors to assess and/or diagnose patients with UD, noting a biphasic pattern or pressure drop at the level of the lesion during the study (Bhatia et al., 1981; Summitt and Stovall, 1992; Wagner et al., 1986).

Alternatively, a small number of patients may have evidence of bladder outlet obstruction on urodynamic evaluation because of the obstructive or mass effects of the UD on the urethra. SUI may coexist with obstruction (Bradley and Rovner, 2004), but nevertheless both conditions can be treated successfully with a carefully planned and executed operation.

Imaging

High-quality preoperative imaging is important in the diagnosis and therapy of female UD. **Aside from its utility as a diagnostic entity, radiologic imaging should also provide an accurate reflection of the relevant anatomy of the UD, including its relationship to the proximal urethra and bladder neck.**

Diagnostic Contrast Radiography

A number of imaging techniques have been applied to the study of female UD, and no single study can be considered the gold standard or optimal imaging study for the evaluation of UD. Each technique has relative advantages and disadvantages, and the ultimate choice of diagnostic study in many centers often depends on several factors, including local availability, cost, and the experience and expertise of the radiologist. Currently available techniques for the evaluation of UD include double-balloon PPU, VCUG, intravenous urography, ultrasonography, and MRI with or without an endoluminal coil.

Historically, **double-balloon PPU** had been considered to be the optimal study for the diagnosis and assessment of female UD (Davis and Cian, 1956; Davis et al., 1958; Ganabathi et al., 1994; Greenberg et al., 1981). In this technique, a highly specialized catheter (Trattner catheter) with two balloons separated by several centimeters is inserted into the female urethra (Fig. 130.20). This catheter contains a channel that exits through a side hole between the two balloons. One balloon is positioned adjacent to the external urethral meatus, and the other balloon is situated at the bladder neck. Both balloons are inflated, creating a seal about the urethral lumen. Contrast is then infused through the channel under slight pressure, distending the urethral lumen between the two balloons and forcing contrast into the UD, thereby opacifying the cavity. **This highly specialized study provides outstanding images of the urethra and UD and importantly, unlike VCUG, is not dependent on the patient successfully voiding during the study.** However, PPU is not widely performed clinically and the specialized Trattner catheter is not widely available.

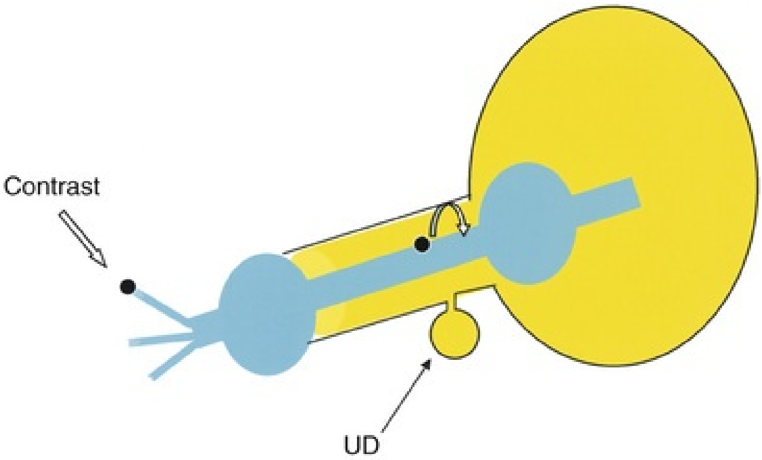

FIG. 130.20 Schematic diagram of a double-balloon catheter. The *curved white arrow* represents flow of the contrast as it enters the urethral lumen. *UD,* Urethral diverticulum.

As an alternative to PPU, **VCUG** may provide excellent imaging of UD (Fig. 130.21). It is widely available and is a familiar diagnostic technique to most radiologists. Sensitivity for UD with this technique varies from 44% to 95% (Ganabathi et al., 1994; Jacoby and Rowbotham, 1999). Patients often will have difficulty in initiating micturition in the radiology suite because of the pain associated with urethral catheterization, psychogenic inhibition attributable to voiding in the presence of others, or other factors. In the absence of voiding, the UD will often not be seen. **Therefore a VCUG that does not demonstrate a UD but did not contain voiding images or postvoid images is nondiagnostic.** If the patient is unable to void under fluoroscopy during the VCUG, an attempt should be made to void in the privacy of an adjacent bathroom. If voiding in private was successful, a postvoid film taken under these circumstances will likely show a collection of contrast inferior to the bladder demonstrating the UD. Unfortunately, an inability to generate an adequate flow rate during the VCUG will result in suboptimal filling of the UD and an underestimation of its size and complexity (Fig. 130.22). Three-dimensional CT VCUG with reconstructions is a novel imaging technique for UD but is not yet widely used clinically (Kim et al., 2005; Lee et al., 2014; Zhao et al., 2017).

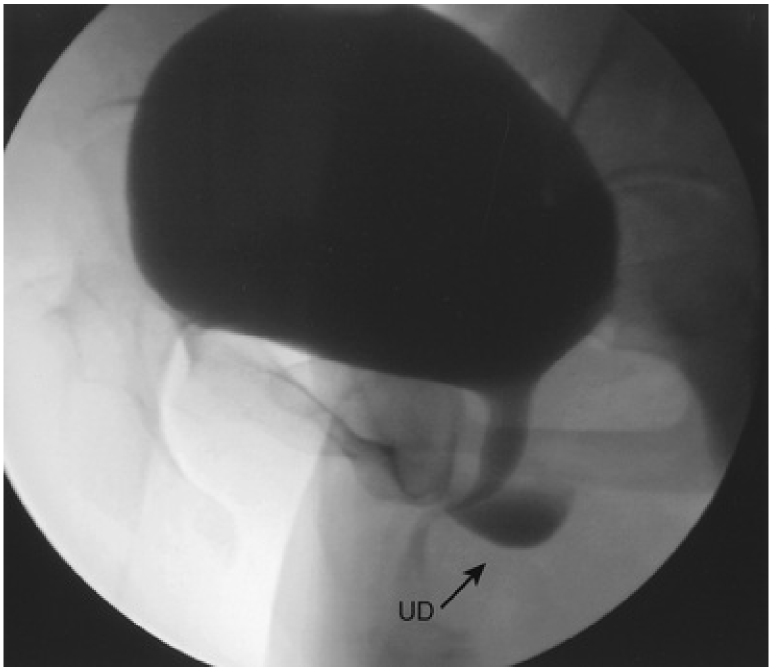

FIG. 130.21 Voiding image from a voiding cystourethrogram demonstrating a urethral diverticulum *(UD).*

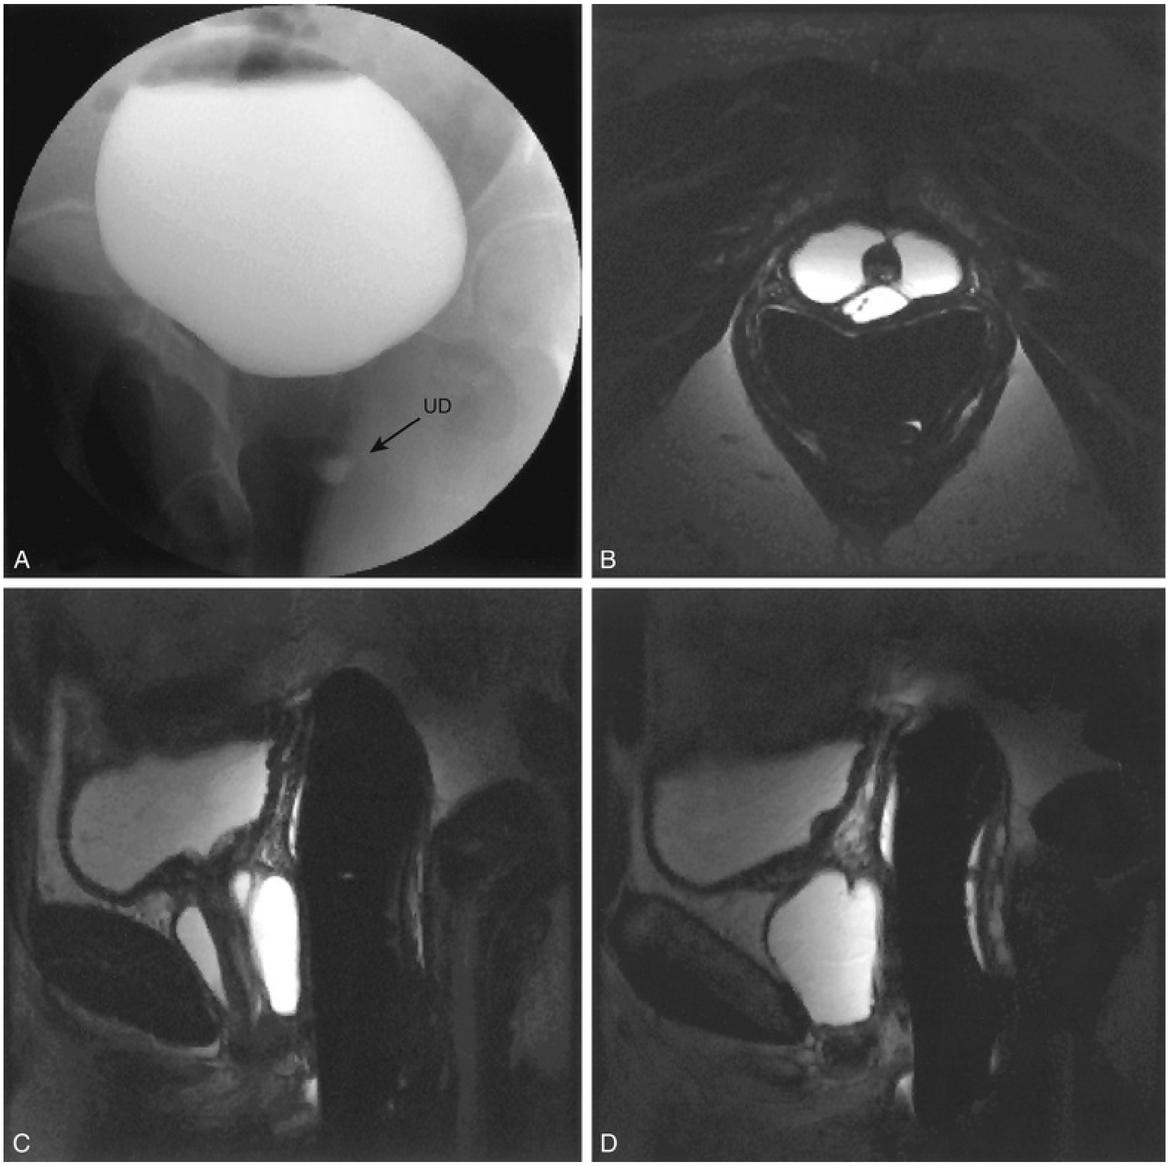

FIG. 130.22 Voiding cystourethrogram (VCUG) and magnetic resonance image (MRI) from a patient with a large circumferential urethral diverticulum *(UD)*. (A) The voiding image from the VCUG shows poor opacification of the proximal urethra with suboptimal distention of the UD as a result of a poor voiding effort. (B to D) The endoluminal MRI demonstrates the full extent and complexity of the lesion on the T2 axial (B), midline sagittal (C), and parasagittal (D) images.

Intravenous urography or CT urogram may be considered in patients in whom it is necessary to delineate the upper urinary tract or to evaluate for the possibility of a congenital ectopic ureteral anomaly as the cause of an anterior vaginal wall mass (Blacklock et al., 1982). The postvoid film of the intravenous urogram can be helpful for the diagnosis of UD in some patients (Goldfarb et al., 1981; Stern and Patel, 1976).

Ultrasonography.

This study has been advocated for the preoperative assessment of vaginal masses and UD by multiple authors (Baert et al., 1992; Chancellor et al., 1995; Dmochowski, 2001; Fortunato et al., 2001; Gerrard et al., 2003; Lee and Keller, 1977; Lee et al., 2001; Mårtensson and Duchek, 1994; Vargas-Serrano et al., 1997; Wexler and McGovern, 1980). Abdominal, transvaginal, translabial, and transurethral techniques have been described. **Transvaginal imaging often provides information regarding the size and location of UD.** On ultrasonographic imaging, the UD appears as an anechoic or hypoechoic area with enhanced through-transmission. Ultrasonography is relatively noninvasive and does not expose the patient to radiation. Another significant advantage of ultrasonography is that successful imaging of UD does not require voiding. However, ultrasonography may not produce detailed high-resolution images that demonstrate precise surgical anatomy. Transvaginal contrast-enhanced sonourethrography has been proposed as a way to improve accuracy of US imaging but requires the use of a catheter, making it as invasive as VCUG, and it requires a skilled sonographer (Dai et al., 2013).

Magnetic Resonance Imaging.

As an alternative to the radiologic investigations noted previously, MRI permits relatively noninvasive, high-resolution, multiplanar imaging of UD. **UD appear as areas of decreased signal intensity on T1 images compared with the surrounding soft tissues and have high signal intensity on T2 images**. **A distinct advantage of MRI compared with VCUG is that successful imaging of UD is wholly independent of voiding and that it is free from ionizing radiation.** Surface coil (Hricak et al., 1991; Kim et al., 1993; Fig. 130.23) and endoluminal (Blander et al., 2001; Lorenzo et al., 2003; Siegelman et al., 1997; Wang and Wang, 1997) techniques have been described. Endoluminal magnetic resonance imaging (eMRI) places the magnetic coil into a body cavity adjacent to the area of interest. This location produces an improved signal-to-noise ratio and high-resolution imaging of these areas (Blander et al., 2001; Siegelman et al., 1997) with excellent sensitivity and specificity for the diagnosis of UD (Dwarkasing et al., 2011). For the evaluation of UD, the eMRI coil is placed intravaginally or intrarectally. **Surface coil MRI and eMRI appear to be superior to VCUG and/or PPU in the evaluation of UD** (Blander et al., 2001; Kim et al., 1993; Neitlich et al., 1998), but the technology is expensive and not widely available. In a series of 17 patients undergoing both PPU and MRI, Portnoy et al. (2013) found that the modalities agreed with 88% correlation on diagnosis of UD, with complexity, location, and demonstration of connection to the urethra also reasonably well correlated (67%, 67%, and 56%, respectively). **Notably, there are several lesions, including periurethral bulking agents, that can be misdiagnosed as UD on MRI** (Gaines et al., 2017)**, and this imaging technique may be inadequate in the diagnosis of malignancy within UD, a rare but important finding** (Chung et al., 2010).

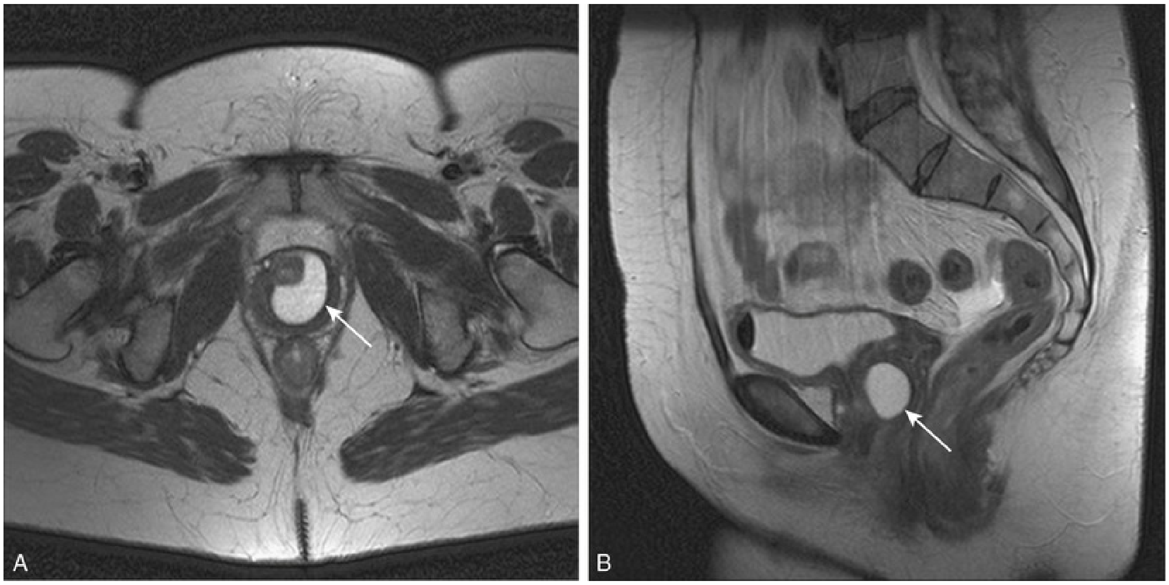

FIG. 130.23 Surface coil T2 magnetic resonance image demonstrating a urethral diverticulum *(arrows)* in the sagittal (A) and axial (B) planes.

Contraindications to MRI for UD are few; these include metallic foreign body fragments, claustrophobia, and an inability to tolerate the endoluminal probe.

Differential Diagnosis: Periurethral Masses Other Than Urethral Diverticula

Periurethral masses other than UD comprise a wide spectrum of conditions that must be differentiated from each other and UD. It may often be possible to make a definitive diagnosis based on history and physical examination alone; in other cases, judicious use of radiographic and cystoscopic studies are necessary to exclude UD.

Vaginal Leiomyoma.

Vaginal leiomyomata are benign mesenchymal tumors of the vaginal wall that arise from smooth muscle elements. They commonly are seen as a smooth, firm, round mass on the anterior vaginal wall (Fig. 130.24). Vaginal leiomyoma is an uncommon lesion, with approximately 300 cases reported in the literature (Young et al., 1991). In a recent series of 79 patients with periurethral masses, 4 (5%) were found to have vaginal leiomyoma (Blaivas et al., 2004). These masses were all apparent on physical examination as freely mobile, firm, nontender masses on the anterior vaginal wall. They may be misdiagnosed as UD (Shirvani and Winters, 2000). Symptoms, if they exist, are usually related to the size of the lesion and include a mass effect, obstruction, pain, and dyspareunia. They commonly occur in the fourth to fifth decade. Similar to uterine leiomyoma, these lesions are usually estrogen dependent and have been demonstrated to regress during menopause (Liu, 1988). Excision or enucleation (Young et al., 1991) through a vaginal approach is often curative and is recommended to confirm the diagnosis, to exclude malignant histology, and also to alleviate symptoms.

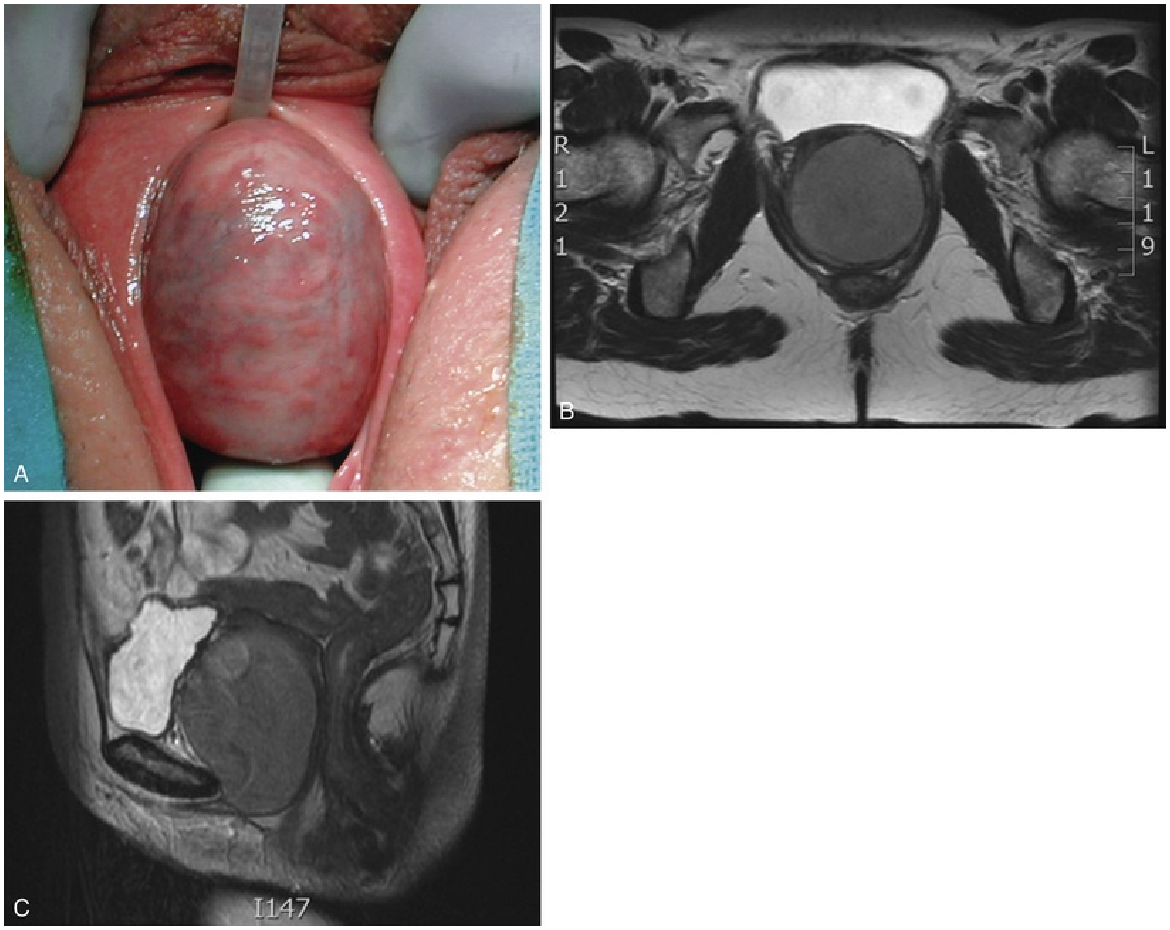

FIG. 130.24 (A) Large anterior vaginal wall leiomyoma. (B and C) Axial (B) and sagittal (C) magnetic resonance images of anterior vaginal wall leiomyoma.

Skene Gland Abnormalities.

Skene gland cysts and abscesses are similar lesions that are differentiated based on clinical findings (Fig. 130.25). Both lesions generally occur as small, cystic masses just lateral or inferolateral to the urethral meatus. They may be lined with transitional or stratified squamous epithelium. Abscesses may be extremely tender and inflamed, and, in some cases, purulent fluid can be expressed from the ductular orifice. **Classically, in contrast to UD, these lesions do not communicate with the urethral lumen.** Skene gland cysts are not uncommonly noted in neonatal girls and young to middle-age female patients (Lee and Kim, 1992). Symptoms may include dysuria, dyspareunia, obstruction, and pain. **Differentiation from UD can often be made on physical examination, because these lesions are located relatively distally on the urethra, often distorting the urethral meatus, as compared with UD, which most commonly occur over the mid- and proximal urethra and do not deform the urethral meatus.** Various treatments for Skene gland abnormalities have been described, including aspiration, marsupialization, incision and drainage, and simple excision. Surgical excision is curative.

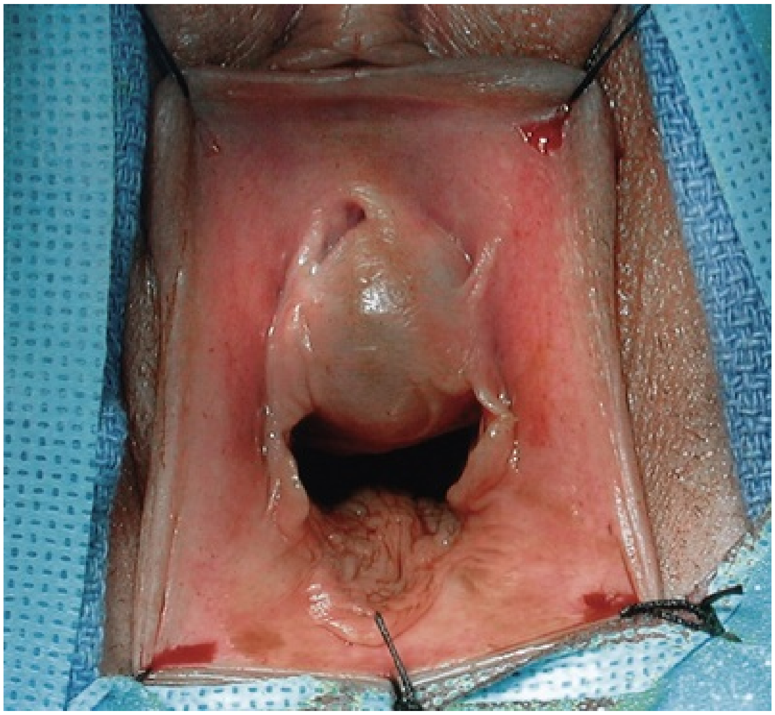

FIG. 130.25 Skene gland cyst in a 19-year-old female. Note the large periurethral mass with displacement of the urethral meatus.

Adenocarcinoma arising in Skene glands has been reported. Because of homology with the prostate, these patients may demonstrate elevated prostate-specific antigen levels that normalize with treatment (Dodson et al., 1994).

Gartner Duct Abnormalities.

Gartner duct cysts represent mesonephric remnants and are found on the anterolateral vaginal wall from the cervix to the introitus. Because these are mesonephric remnants, they may drain ectopic ureters from poorly functioning or nonfunctioning upper pole moieties in duplicated systems (Fig. 130.26). They have also been reported with single-system ectopia, although this is much less common in females (Currarino, 1982; Gadbois and Duckett, 1974). **It is not clear what proportion of patients with Gartner duct cysts will have ipsilateral renal abnormalities, but upper tract evaluation is recommended.** In contrast, approximately 6% of subjects with unilateral renal agenesis have a Gartner duct cyst (Eilber and Raz, 2003). Up to 50% of patients with Gartner duct cysts and renal dysplasia may also have ipsilateral müllerian duct obstruction (Sheih et al., 1998).

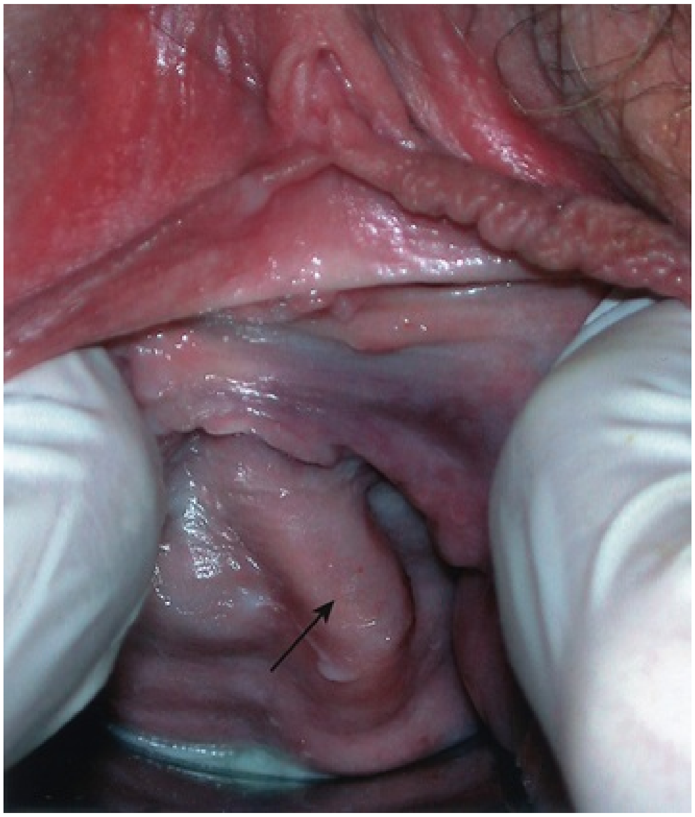

FIG. 130.26 Upper pole ectopic ureter in a 39-year-old female being evaluated for lifelong urinary incontinence and recurrent pyelonephritis. A tubelike structure *(arrow)* representing the turgid, debris-filled ectopic ureter is seen on the anterior vaginal wall.

Treatment depends on symptoms and association with ectopic ureters. If the lesions are asymptomatic and are associated with a nonfunctioning renal moiety, they can be observed. Aspiration followed by sclerotherapy has been successful (Abd-Rabbo and Atta, 1991). Simple excision or marsupialization has also been recommended for symptomatic lesions. If the cyst is associated with a functioning renal moiety, treatment must be individualized.

Vaginal Wall Cysts.

Vaginal wall cysts usually occur as small asymptomatic masses on the anterior vaginal wall (Deppisch, 1975) but may enlarge to cause lower urinary tract symptoms or dyspareunia (Fig. 130.27). They may arise from multiple cell types: mesonephric (Gartner duct cysts), paramesonephric (müllerian), endometriotic, urothelial, or epidermoid (inclusion cyst). A specific diagnosis cannot be reliably made until the specimen is removed and examined by a pathologist. The histologic subtype is usually of little consequence, although epidermoid cysts are usually associated with previous trauma or vaginal surgery. Pradhan and Tobon described the pathological characteristics of 43 vaginal cysts removed over a 10-year period from 41 women (Pradhan and Tobon, 1986). The derivation of the cyst was müllerian in 44%, epidermoid in 23%, and mesonephric in 11%. The remainder were a Bartholin gland type, endometriotic, and indeterminate. As with other periurethral masses, they must be differentiated from UD. Treatment is usually by simple excision in symptomatic patients.

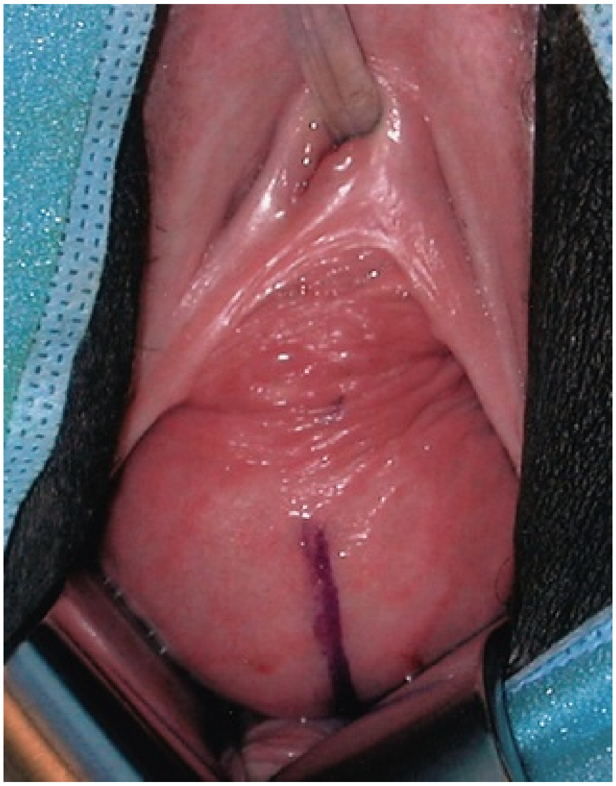

FIG. 130.27 Anterior vaginal wall cyst before planned excision. This mass was misdiagnosed as a cystocele and followed for many years in this patient with considerable lower urinary tract symptoms. A midline incision has been marked out before operative repair.

Urethral Mucosal Prolapse.

Urethral prolapse is seen as a circumferential herniation or eversion of the urethral mucosa at the urethral meatus. The prolapsed mucosa commonly appears as a beefy red, doughnut-shaped lesion that completely surrounds the urethral meatus. It may be asymptomatic or occur with bleeding, spotting, pain, or urinary symptoms. **It is commonly noted in two separate populations:**

postmenopausal women and prepubertal girls. Although thought to be more common in young African-American girls, more recent series do not confirm this predilection (Fernandes et al., 1993; Rudin et al., 1997). In children, it is often causally related to Valsalva voiding or constipation. Eversion of the mucosa may then occur as a result of a pathologically loose attachment between smooth muscle layers of the urethra (Lowe et al., 1986). Cause is much less clear for postmenopausal women, although it has been epidemiologically linked to estrogen deficiency. Treatment may be medical or surgical. **Medical treatment involves topical creams (estrogen, anti-inflammatory) and/or sitz baths. Various surgical techniques have been described, including cauterization, ligation around a Foley catheter, and complete circumferential excision.** Circumferential excision with suture reapproximation of the remaining urethral mucosa to the vaginal wall can be performed with few complications. Rudin et al. (1997) reported outcomes in 58 girls with urethral prolapse. Medical treatment was initially successful in 20 patients among whom there were 5 recurrences. The remaining 38 patients failed initial conservative management and underwent surgical excision with 4 complications, including urethral stenosis in 2 patients. Jerkins et al. (1984) found superior results in surgically treated patients when compared with medical management or catheter ligation.

Urethral Caruncle.

Urethral caruncle is an inflammatory lesion of the distal urethra that is most commonly diagnosed in postmenopausal women. It usually appears as a reddish exophytic mass at the urethral meatus, which is covered with mucosa. These lesions are often symptomatic and noted incidentally on gynecologic examination. When irritated, they may cause underwear spotting or become painful. Less commonly they may cause voiding symptoms. Rarely, these lesions may thrombose, resulting in a discolored periurethral mass (Fig. 130.28). **Etiologically, they are related to mucosal prolapse.** Chronic irritation contributes to hemorrhage, necrosis, and inflammatory growth of the tissue that corresponds to the histology of excised lesions. If the lesion is atypical in appearance or behavior, excision may be warranted to exclude other entities. Intestinal metaplasia, tuberculosis, melanoma, and lymphoma have been reported to either coexist with or mimic urethral caruncles (Atalay et al., 1998; Indudhara et al., 1992; Khatib et al., 1993; Lopez et al., 1993; Willett and Lack, 1990).

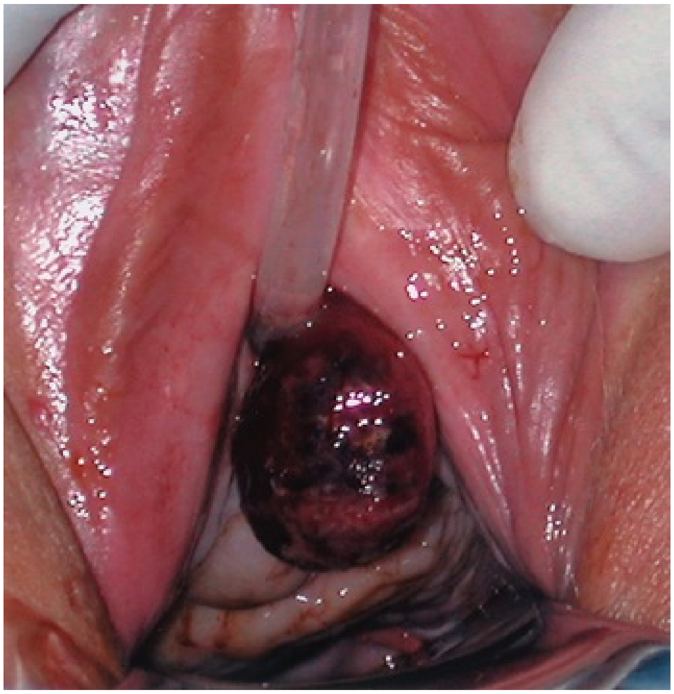

FIG. 130.28 Thrombosed urethral caruncle in a postmenopausal female. The Foley catheter is seen in the urethra. Simple excision was curative.

There is a paucity of literature regarding optimal treatment of urethral caruncle. Most authors recommend initial conservative management with topical estrogen or anti-inflammatory creams and sitz baths. Large or refractory lesions may be managed with simple excision. The tip of the lesions should be grasped and traction employed to fully expose the base of the caruncle. The lesion can then easily be excised. If a large defect remains, the mucosa may be reapproximated with absorbable suture. In most instances, the urethral mucosa will heal around a Foley catheter, which may be left in place for several days.

Periurethral Bulking Agents.

The transurethral or periurethral injection of bulking agents for the treatment of stress incontinence may result in an anterior vaginal wall mass that appears cystic on imaging, consistent with a UD (Bridges et al., 2005; Castillo-Vico et al., 2007; Clemens and Bushman, 2001). These radiographic lesions are often misdiagnosed as such (Gaines et al., 2017). A careful history will elicit this possibility. Typically, these lesions do not communicate with the urethra and are largely asymptomatic. Symptomatic lesions may be surgically excised transvaginally (Kumar et al., 2011).

Classification of Urethral Diverticula

Although not yet widely adopted, a classification system for UD has been proposed by Leach et al. (1993).This staging system for UD, termed the *L/N/S/C3 classification system*, is similar to that used for cancer staging and is based on several characteristics of UD, including location, number, size, anatomic configuration, site of communication to the urethral lumen, and continence status of the patient. This system attempts to standardize description of UD, but currently it has not been prospectively applied or validated by other authors. Another proposed classification scheme uses the location of the UD as the primary determinant of surgical approach, with distal lesions undergoing marsupialization and more proximal lesions undergoing excision and reconstruction (Ginsburg and Genadry, 1983).

Finally, a classification system proposed by Leng and McGuire divides UD into two categories based on the presence or absence of a preserved periurethral fascial layer (Leng and McGuire, 1998). In some patients with UD who have undergone prior vaginal or urethral surgery, the periurethral fascial layer may be deficient, resulting in a pseudodiverticulum. These authors suggest that the recognition of this anatomic configuration has important implications for surgical reconstruction. These patients may require additional reconstruction or interposition of a tissue flap or graft for reconstruction.

Key Points: Female Urethral Diverticula: Diagnosis

- Female UD are often diagnosed in the evaluation of nonspecific lower urinary tract symptoms, including dysuria, pelvic pain, vaginal mass, dyspareunia, and recurrent UTIs.
- Multiple imaging modalities may be used in the diagnosis and evaluation of female UD, including PPU, VCUG, ultrasonography, and MRI; each of these techniques has inherent advantages and disadvantages.
- The differential diagnosis of periurethral vaginal masses is extensive. A careful history, physical examination, and appropriate diagnostic studies are usually adequate to provide a definitive preoperative diagnosis.

Surgical Repair of Female Urethral Diverticula

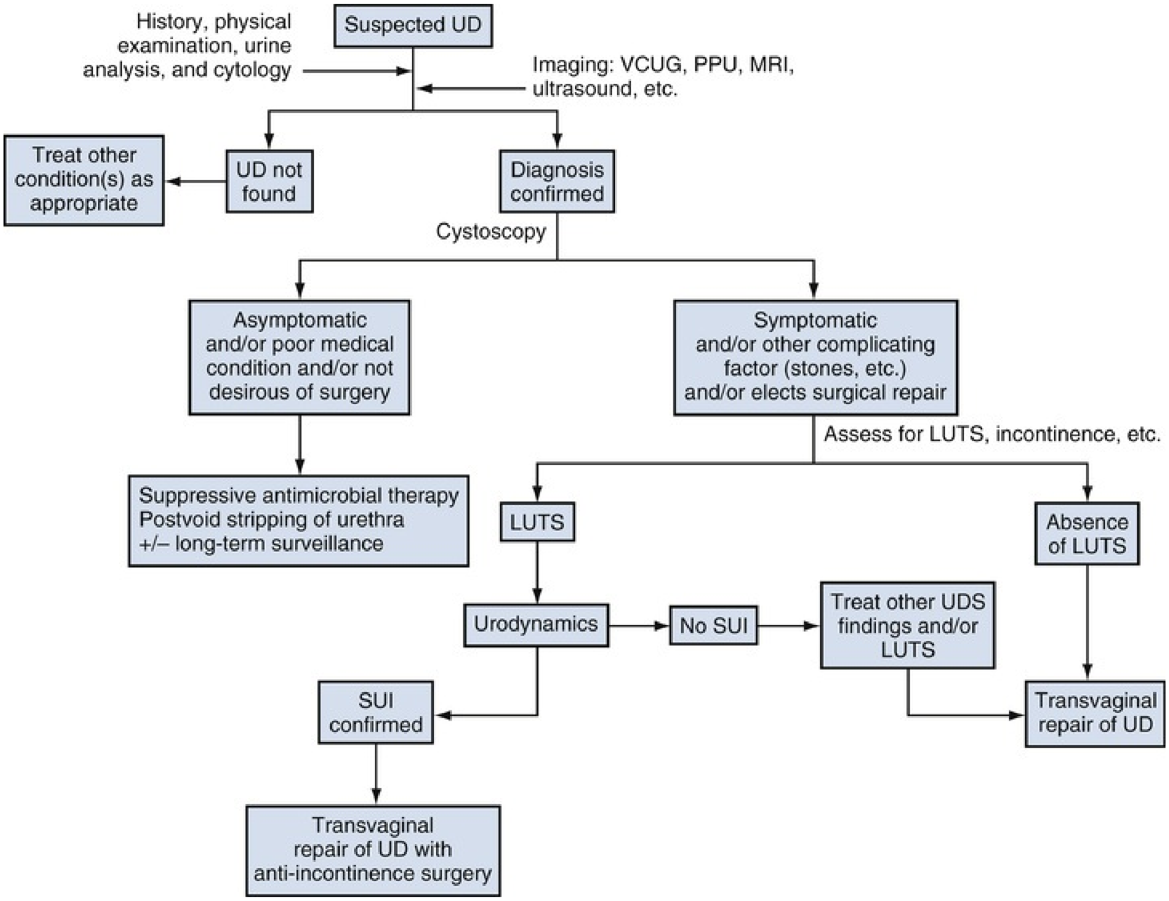
Indications for Repair

Although often highly symptomatic, not all UD mandate surgical excision. Some patients may be asymptomatic at presentation, with the lesion incidentally diagnosed on imaging for another condition or, perhaps, incidentally noted on routine physical examination. Other patients may be unwilling or medically unable to undergo surgical removal. **Very little is known regarding the natural history of untreated UD. Whether these lesions will progress in size, symptomatology, or complexity with time is unknown.** For these reasons, lack of symptoms in selected cases, and the risks of surgical intervention including de novo urinary incontinence, urethral stricture, and vaginal scarring, some patients may not desire surgical excision. However, **there are multiple reports in the literature of carcinomas arising in UD** (Gonzalez et al., 1985; Hickey et al., 2000; Marshall and Hirsch, 1977; Patanaphan et al., 1983; Prudente de Toledo et al., 1978; Rajan et al., 1993; Seballos and Rich, 1995; Tesluk, 1981; Thomas and Maguire, 1991; Tines et al., 1982). It is possible that certain carcinomas arising in UD are asymptomatic and may not be initially or prospectively identified on radiologic imaging (Chung et al., 2010). **Thus patient counseling is necessary with patients who elect primary nonoperative management.** Patients electing nonoperative management can be treated with low-dose antibacterial suppressants and digital stripping of the anterior vaginal wall after micturition to prevent postvoid dribbling and reduce the risk of UTI resulting from stasis in the UD. Whether long-term surveillance for the development of cancer is required in these patients, with periodic physical examinations, radiographic imaging, or endoscopic examination, is unknown.

Symptomatic patients, including those with dysuria, refractory bothersome postvoid dribbling, recurrent UTIs, dyspareunia, and pelvic pain, may be offered surgical excision.

Urethral Diverticula and Stress Urinary Incontinence

As noted previously SUI may co-exist with UD. In addition, significant de novo SUI may occur in between 7% and 16% of individuals undergoing urethral diverticulectomy surgery without a concomitant anti-incontinence surgery (Han et al., 2007; Ljungqvist et al., 2007; Reeves et al., 2014; Stav et al., 2008). Lee et al. (2008) noted at least minor de novo SUI in 49% of patients after urethral diverticulectomy, the majority of which was minor and did not require additional therapy. In this series, only 10% of affected individuals underwent a subsequent SUI operation (Lee et al., 2008). Risk factors for de novo SUI may include the size of the diverticulum (>30 mm), more proximal location (Kim et al., 2013; Stav et al., 2008), as well as circumferential configuration (Malde et al., 2017). Furthermore, in a retrospective review of MRI findings, Malde et al. (2017) suggest that a complex circumferential UD configuration is associated with a greater risk of postoperative SUI (20%) as compared with a simple UD (0) in the absence of a concomitant anti-incontinence procedure, but this has not been consistently found in the literature (Nickles et al., 2014). However, it is not universally agreed that all UD patients should undergo simultaneous SUI surgery. The additional operative time and expense, as well as the potential morbidity of concomitant SUI surgery, should be balanced against the convenience of performing both surgeries synchronously. **Nevertheless, for patients undergoing surgery for UD who have coexistent symptomatic bothersome SUI, a concomitant anti-incontinence surgery can be offered** (Fig. 130.29). Multiple authors have described successful repair of UD and stress incontinence in the same operative setting (Bass and Leach, 1991; Faerber, 1998; Ganabathi et al., 1994; Lockhart et al., 1990; Swierzewski and McGuire, 1993). Patients without SUI or who have mild non-bothersome SUI can be counseled that it is reasonable to perform urethral diverticulectomy surgery alone, and then re-evaluate later for the development of bothersome postoperative SUI after recovery from the UD surgery (Greiman et al., 2018).



History, physical examination, urine analysis, and cytology
Suspected UD
Imaging: VCUG, PPU, MRI, ultrasound, etc.
Treat other condition(s) as appropriate
UD not found
Diagnosis confirmed
Cystoscopy
Asymptomatic and/or poor medical condition and/or not desirous of surgery
Symptomatic and/or other complicating factor (stones, etc.) and/or elects surgical repair
Assess for LUTS, incontinence, etc.
Suppressive antimicrobial therapy
Postvoid stripping of urethra
+/– long-term surveillance
LUTS
Absence of LUTS
Urodynamics
No SUI
Treat other UDS findings and/or LUTS
SUI confirmed
Transvaginal repair of UD
Transvaginal repair of UD with anti-incontinence surgery

FIG. 130.29 Algorithm for treatment of urethral diverticula. *LUTS,* Lower urinary tract symptoms; *MRI,* magnetic resonance imaging; *PPU,* positive-pressure urethrography; *SUI,* stress urinary incontinence; *UD,* urethral diverticulum; *UDS,* urodynamics; *VCUG,* voiding cystourethrography.

Synthetic materials (e.g., mid-urethral polypropylene mesh) should not be used in an anti-incontinence procedure synchronously with UD surgery because of the potentially increased risk of urethral erosion and infection (Dmochowski et al., 2010). Whether such material can be safely used months or years after successful UD surgery in patients with de novo or persistent SUI is unknown. Contemporary series have demonstrated that autologous pubovaginal fascial slings provide satisfactory outcomes as a concomitant procedure at the time of UD excision (Enemchukwu et al., 2015; Faerber, 1998; Romanzi et al., 2000; Swierzewski and McGuire, 1993).

Techniques for Repair

Alternative Techniques.

A variety of surgical interventions for UD have been reported since 1805 when Hey described transvaginal incision of the UD and packing the resulting cavity with lint. Approaches have included transurethral (Davis et al., 1970) and open (Roehrborn, 1988; Spence and Duckett, 1970) marsupialization, endoscopic unroofing (Lapides, 1978; Spencer and Streem, 1987), fulguration (Saito, 2000), incision and obliteration with oxidized cellulose (Ellick, 1957) or polytetrafluoroethylene (Mizrahi and Bitterman, 1988), coagulation (Mizrahi and Bitterman, 1988), and excision with reconstruction. **Most commonly, a complete excision and reconstruction is performed as described later.** However, for distal lesions, a transvaginal marsupialization as described by Spence and Duckett may reduce operative time, blood loss, and recurrence rate (Roehrborn, 1988; Spence and Duckett, 1969, 1970). **During this procedure, care must be taken to avoid aggressively extending the incision proximally, which could result in vaginal voiding or potentially damage the proximal and distal sphincteric mechanism, resulting in SUI.** Another potentially significant complication with the Spence-Duckett procedure is that, in sexually active women, a pseudoseptum may be created by the marsupialization of the urethra with respect to the anterior vaginal wall, which may result in dyspareunia. Therefore this approach is probably only applicable to UD in very select cases involving the distal one-third of the urethra in patients who are not sexually active. It is not commonly performed.

Excision and Reconstruction.

Excision and reconstruction is probably the most common surgical approach to UD in the modern era. The principles of the urethral diverticulectomy operation have been well described (Box 130.2). There are only a few minor issues about which some surgeons may disagree, including the type of vaginal incision (midline vs. inverted “U” vs. inverted “T”), whether it is necessary to remove the entire mucosalized portion of the lesion, and, finally, the optimal type of postoperative catheter drainage (urethra only vs. urethra and suprapubic tube).

Box 130.2

Principles of Transvaginal Urethral Diverticulectomy

Mobilization of a well-vascularized anterior vaginal wall flap(s)
Preservation of the periurethral fascia as a separate layer
Identification and excision of the neck or ostium of the UD
Removal of entire UD wall or sac (epithelium)
Watertight urethral closure
Multilayered, nonoverlapping closure with absorbable suture
Closure of dead space
Preservation or creation of continence

UD, Urethral diverticulum.

Complex urethral reconstructive techniques for the repair of UD have been described. Fall (1995) described the use of a bipedicled vaginal wall flap for urethral reconstruction in patients with UD and urethrovaginal fistula. Laterally based vaginal flaps have also been used as an initial approach to UD (Appell et al., 1982; Woodhouse et al., 1980). Complex anatomic configurations may exist, and many novel approaches have been described for complicated anteriorly located or circumferential lesions (Clyne and Flood, 2002; Rovner and Wein, 2003; Vakili et al., 2003). Recently, a laparoscopic/robotic approach to an anterior urethral diverticulum has been described (Sivarajan et al., 2015).

The technique described herein is similar to that described by Leach et al. (1986), based on earlier work by Benjamin et al. (1974) and Busch and Carter (1973). A systematic review of surgical techniques for treating UD in 1947 patients determined that the literature lacks sufficient data to describe differences in outcomes and complications among the surgical techniques (Bodner-Adler et al., 2016). A systematic review of surgical techniques for treating urethral diverticula in 1947 patients determined that the literature lacks sufficient data to describe differences in outcomes and complications among the surgical techniques (Bodner-Adler et al., 2016).

Preoperative Preparation.

The urine should be sterile preoperatively. Surgery should not proceed in the setting of an acute UTI. Prophylactic antibiotics are often used preoperatively to ensure sterile urine at the time of surgery. Patients can also be encouraged to strip the anterior vaginal wall after voiding, thereby consistently emptying the UD and preventing urinary stasis and recurrent UTIs. This may not be possible in those with noncommunicating UD or in those who have significant pain related to the UD. **In some patients with postmenopausal atrophic vaginitis, application of topical estrogen creams for several weeks before surgery may be beneficial in improving the overall quality of the tissues with respect to planned operative dissection and mobilization. Preoperative parenteral antibiotics are administered especially for those with recurrent or persistent UTIs.**

Urethral diverticulectomy surgery is complex and sometimes technically challenging. Further complicating these cases are the associated preoperative symptoms such as pain, dyspareunia, voiding dysfunction, UTIs, and urinary incontinence. These associated symptoms are often, but not always, improved or eliminated with surgical repair despite a technically successful surgery. Therefore the importance of appropriate preoperative patient counseling regarding surgery and postoperative expectations of cure cannot be overemphasized.

As noted previously, patients with symptomatic SUI can be offered simultaneous anti-incontinence surgery. Preoperative video-urodynamics may be helpful in evaluating the anatomy of the UD, assessing the competence of the bladder neck, and confirming the diagnosis of SUI. Video-urodynamics can often accurately differentiate and characterize true SUI from postvoid dribbling, vaginal voiding, and false incontinence resulting from urine discharge from a urine-filled UD.

Procedure.

The patient is placed in the lithotomy position with all pressure points well padded. The use of padded adjustable stirrups for the lower extremities greatly enhances operative access to the female perineum. A standard vaginal antiseptic preparation is applied. A weighted vaginal speculum and Scott retractor with hooks aid in exposure. **A posterolateral episiotomy may be beneficial in some patients for additional exposure, although the mid-urethral (and therefore somewhat distal in the vaginal canal) location of most UD usually precludes the need for this type of adjunctive procedure.** A Foley catheter is placed per urethra. If desired, a suprapubic tube is placed at the start of the procedure, either using the Lowsley retractor or proceeding percutaneously under direct transurethral cystoscopic visual guidance. Placement of the suprapubic tube at the end of the case is not advisable because this will require traversing the fresh urethral suture line and risk disruption of the repair.

An inverted U is marked along the anterior vaginal wall with the base of the U at the level of the distal urethra and the limbs extending to the bladder neck or beyond (Fig. 130.30A). Care is taken to ensure that the limbs of the U are progressively wider proximally (toward the bladder neck) to ensure adequate vascularity at the distal lateral margins of the anterior vaginal wall flap. Compared with the inverted T incision, the inverted U incision provides excellent exposure laterally at the level of the mid-vagina and can be extended proximally as needed for lesions that extend beyond the bladder neck. Injectable saline can be infused along the lines of the incision to facilitate dissection. An anterior vaginal wall flap is created by careful dissection in the potential space between the vaginal wall and the periurethral fascia. **The use of sufficient countertraction during this portion of the procedure is important in maintaining the proper plane of dissection. Care is taken to preserve the periurethral fascia and avoid inadvertent entry into the UD.**

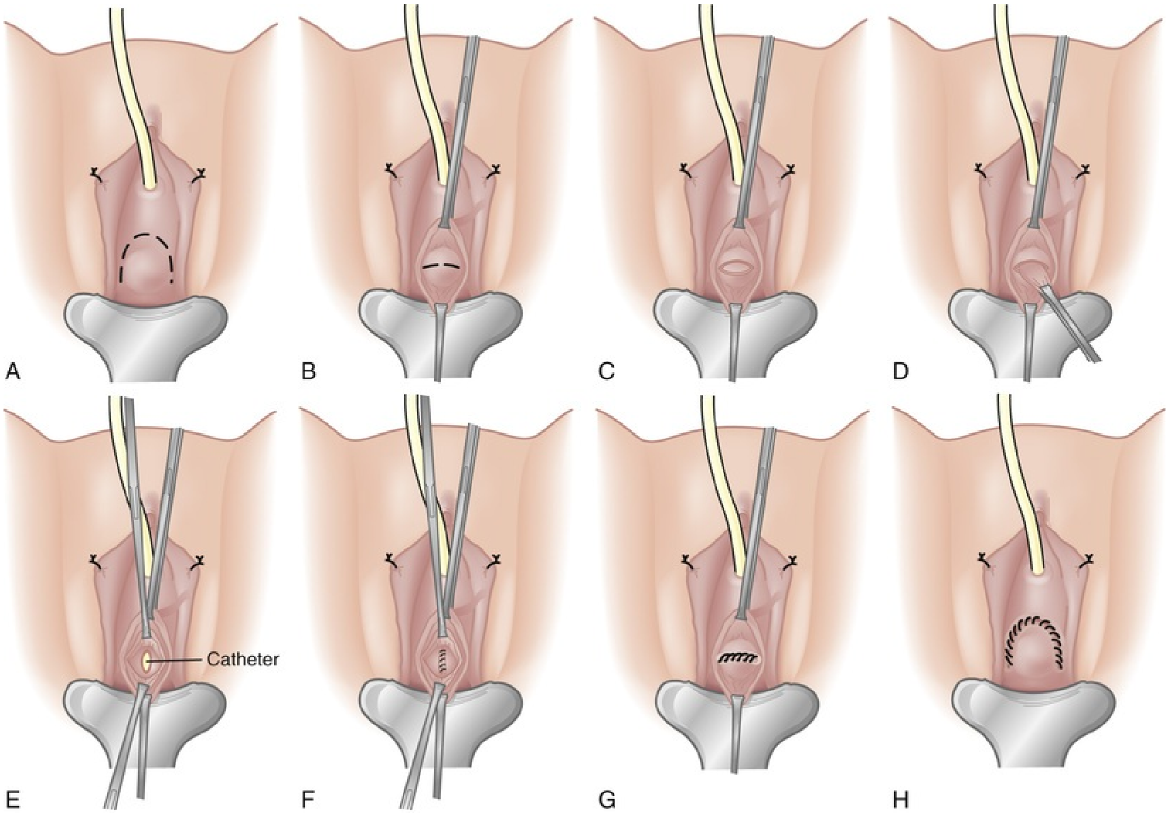


FIG. 130.30 (A) An inverted U incision is marked on the anterior vaginal wall. Retraction is aided by the use of Allis clamps and a ring retractor with hooks. (B) After reflection of the anterior vaginal wall, a transverse incision is made in the periurethral fascia. The *dotted line* represents the intended incision line. (C) The periurethral fascia is incised and dissected from the underlying urethral diverticulum. (D) The diverticular sac is freed from the

periurethral fascia. (E) The urethral catheter is seen after complete excision of the diverticular sac. (F) The urethra is closed with absorbable suture. (G) The periurethral fascia is closed with care to obliterate any dead space. (H) The anterior vaginal wall flap is advanced over the periurethral suture line and secured with running interlocking absorbable suture.

A distinct layer of periurethral fascia is usually interposed between the vaginal wall and the UD. Preservation and later reconstruction of this layer is paramount to prevent recurrence, close dead space, and avoid urethrovaginal fistula formation postoperatively. Pseudodiverticula have been described wherein this layer of tissue is considerably attenuated or even absent (Leng and McGuire, 1998). In these patients, an interpositional Martius flap or a graft such as a pubovaginal fascial sling may be used for reconstruction.

The periurethral fascia is incised transversely (Fig. 130.30B). Proximal and distal layers of periurethral fascia are carefully developed, avoiding entrance into the UD. The UD is then grasped and dissected back to its origin on the urethra within the leaves of the periurethral fascia (Fig. 130.30C). In many cases, it is necessary to open the UD to facilitate dissection from the surrounding tissues. The ostium or connection to the urethra is identified and the walls of the UD are completely removed. Every effort should be made to remove the entire mucosalized surface of the UD to prevent recurrence (Fortunato et al., 2001; Ganabathi et al., 1994). This may involve removing small adherent or inflamed portions of the urethral wall, especially in the area of the ostium (Fig. 130.30D). All abnormal tissue in the area of the ostium should be removed, if possible, to ensure that no mucosal elements of the UD wall remain, which could result in postoperative urine leakage and recurrence. Elaborate methods of identifying the full extent of the UD cavity have been described, including catheterization of the UD with urinary (Kohorn and Glickman, 1992; Moore, 1952) and Fogarty (Wear, 1976) catheters, packing the UD with gauze (Hyams and Hyams, 1939), infusing and staining the UD with methylene blue (Gilbert and Rivera Cintron, 1954), and the use of silicone (Hirschhorn, 1964) or cryoprecipitate (Feldstein, 1981) to create a solid mass and ease dissection. However, these measures are mostly of historical interest only and are usually not necessary in modern UD surgery (Ganabathi et al., 1994; Leach and Bavendam, 1987).

The Foley catheter is often seen transvaginally through the operative site after complete excision of UD (Fig. 130.30E). The urethra can be reconstructed over as small as a 12-Fr Foley catheter without long-term risk of urethral stricture (Young and Wahle, 1996) and should be closed in a watertight fashion with absorbable suture (Fig. 130.30F). The closure should be tension free. Uncommonly, a UD may extend circumferentially around the urethra and require segmental resection of the involved portion of the urethra and complex reconstruction (Rovner and Wein, 2003; Tamada et al., 2000).

The periurethral fascial flaps are reapproximated with absorbable suture in a perpendicular orientation to the urethral closure line to minimize overlap and the risk of postoperative urethrovaginal fistula formation (Fig. 130.30G). Care is taken to secure the periurethral fascial flaps so that all dead space is closed.

If desired, a fibrofatty labial (Martius) flap can be harvested at this point and placed over the periurethral fascia as an additional layer of closure (Dmochowski, 2001). **Indications for such a flap are not universally agreed upon. However, in those patients with poor-quality tissues, with attenuated periurethral fascia, or in whom significant inflammation is encountered intraoperatively, a well-vascularized adjuvant flap (e.g., Martius flap) may reduce the risk of wound breakdown and subsequent complications such as urethrovaginal fistula.** Malde et al. (2017a,b) report a low rate of complication for Martius flap (<2%) with good cosmetic results.

The anterior vaginal wall flap is then repositioned and reapproximated with absorbable suture (Fig. 130.30H). This completes a three-layer closure (four layers if a Martius flap is used). An antibiotic-impregnated vaginal pack is placed.

For the rare anteriorly located UD without a posterior component, a suprameatal, infrapubic incision is made, and the dissection and reconstruction proceed as described earlier with the same principles including removal of the diverticulum, identification and closure of the ostia, and re-approximation of the periurethral fascia.

Postoperative Care.

Antibiotics are continued for 24 hours postoperatively. The vaginal packing is removed and the patient discharged home with closed urinary drainage. Antispasmodics are used liberally to reduce bladder spasms. A pericatheter VCUG is obtained at 14 to 21 days postoperatively. If there is no extravasation, the catheters are removed. If extravasation is seen, then repeat pericatheter VCUGs are performed weekly until resolution is noted. In the vast majority of cases, extravasation will resolve in several weeks with this type of conservative management (Schwab and Rovner, 2003).

Complications.

Careful adherence to the principles of transvaginal urethral diverticulectomy should minimize postoperative complications. Nevertheless, complications may arise (Table 130.2). Raup et al. (2015) described 30-day complications of diverticulectomy in the multi-institutional cohort derived from the National Surgical Quality Improvement Program user files. They found that out of 2.3 million cases in the database, there were 122 female urethral diverticulectomy cases reported between 2007 and 2012. Minor complications occurred in 3.3% of cases, with urinary tract infection being most common (4 patients), and one each of superficial wound infection and hemorrhage requiring transfusion (Raup et al., 2015).

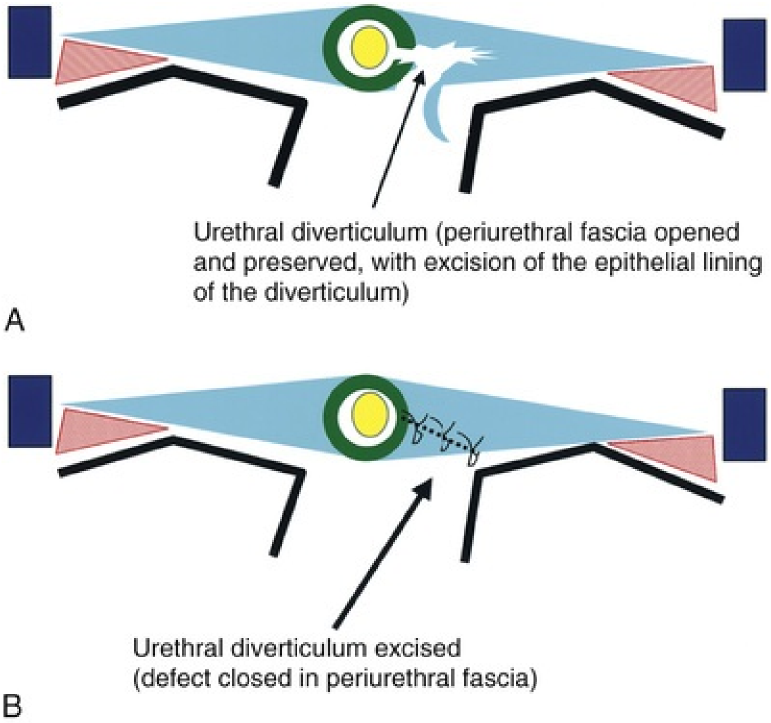
TABLE 130.2

Complications of Transvaginal Urethral Diverticulectomy

COMPLICATION	RANGE OF REPORTED INCIDENCE
Urinary incontinence	1.7%–16.1%
Urethrovaginal fistula	0.9%–8.3%
Urethral stricture	0–5.2%
Recurrent urethral diverticula	10%–22%
Recurrent urinary tract infection	0–31.3%
Other:	
Hypospadias/distal urethral necrosis	Not available
Bladder or ureteral injury	Not available
Vaginal scarring or narrowing: dyspareunia, etc.	Not available

Modified from Dmochowski R: Surgery for vesicovaginal fistula, urethrovaginal fistula, and urethral diverticulum. In Walsh PC, Retik AB, Vaughan ED Jr, et al., editors: *Campbell's urology*, ed 8, Philadelphia, 2002, Saunders.

Overall, common complications include recurrent UTIs, urinary incontinence, or recurrent UD. Urethrovaginal fistula is an uncommon but distressing complication of urethral diverticulectomy and deserves special mention. A urethrovaginal fistula located beyond the sphincteric mechanism should not be associated with symptoms other than perhaps a split urinary stream and/or vaginal voiding. Therefore an asymptomatic distal urethrovaginal fistula may not require repair, although some patients may request repair. Conversely, a proximal fistula located at the bladder neck or at the mid-urethra in patients with an incompetent bladder neck will likely result in considerable symptomatic urinary leakage. These patients should undergo repair with consideration for the use of an adjuvant tissue flap, such as a Martius flap, to provide a well-vascularized additional tissue layer if needed. The actual timing of the repair relative to the initial procedure is controversial. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of the periurethral fascia (Fig. 130.31), a well-vascularized anterior vaginal wall flap, and a multilayered closure with nonoverlapping suture lines should minimize the potential for postoperative urethrovaginal fistula formation.



Urethral diverticulum (periurethral fascia opened and preserved, with excision of the epithelial lining of the diverticulum)

Urethral diverticulum excised (defect closed in periurethral fascia)
B

FIG. 130.31 Diagrams demonstrating the importance of preserving and reconstructing the periurethral fascia. (A) The periurethral fascia has been opened and the urethral diverticulum has been excised. (B) The periurethral fascia has been closed.

One small series suggested that large diverticula (>4 cm) or those associated with a lateral or horseshoe configuration may be associated with a greater likelihood of postoperative complications (Porpiglia et al., 2002), whereas other series (Nickles et al., 2014) show similar complication rates, except for increased rate of UTI after repair of complex diverticula as compared with simple diverticula.

Persistence or Recurrence of Symptoms After Urethral Diverticulectomy.

Although complete resolution of obstructive and irritative urinary symptoms after UD excision may occur, some patients have persistence or recurrence of their preoperative symptoms postoperatively (Bodner-Adler et al., 2016; Stav et al., 2008). These symptoms may be a result of surgery, and if so, may resolve over time. Such symptoms should be carefully investigated, because they could result from a recurrent UD, a new UD, or urethral stricture among other possibilities.

Lack of resolution of some or all symptoms after UD surgery may occur in a substantial number of patients regardless of anatomic complexity of the UD, surgical approach, or technically successful excision (Nickles et al., 2014). One series suggests that excision of recurrent UD are associated with less likelihood of resolution of preoperative symptoms (Ljungqvist et al., 2007).

The finding of a UD after a presumably successful urethral diverticulectomy may occur as a result of a new UD, or, alternatively, as a result of recurrence of the original lesion. Recurrence of UD may be due to incomplete removal of the UD, inadequate closure of the urethra or residual dead space, or other technical factors. The risk of long-term recurrence is approximately 10% to 22% (Han et al., 2007; Ingber et al., 2011; Ko et al., 2017; Lee, 1983; Ljungqvist et al., 2007; Popat and Zimmern, 2016; Zhou et al., 2017). Lee noted recurrent UD in 8 of 85 patients at follow-up of 2 to 15 years from the initial UD resection (Lee, 1983), whereas Ljungqvist et al. (2007) reported recurrence in 11 of 68 patients during a 26-year follow-up. The risk of recurrence of UD after transvaginal excision may be related to the complexity of the anatomic configuration and location. Han et al. (2007) reported no recurrent UD in 17 patients with simple UD, but of the 10 patients with circumferential UD, recurrence was noted in 6 (60%). Notably in this series, secondary procedures were not as successful in completely removing the UD (Han et al., 2007). Ockrim et al. (2009) similarly cured all 19 patients with simple UD on the first attempt, but the 11 patients with complex anatomic configurations required a total of 17 procedures for success. Popat and Zimmern (2016) reported a series of 12 patients with horseshoe diverticula with recurrence in 1 patient with a mean follow-up of 52 months. Ko et al. (2017) reported a series of 68 patients with a recurrence rate of 22% for primary urethral diverticulectomy, and multivariate analysis showed that circumferential configuration was independently associated with recurrence. Proximal location and multiple UD at presentation are also potential risk factors for recurrence

(Ingber et al., 2011). In a meta-analysis of contemporary series, Cameron (2015) reported the rate of diverticulum recurrence after surgical repair to be 9.8%. **Repeat urethral diverticulectomy surgery can be challenging because of altered anatomy, scarring, and the difficulty in identifying the proper anatomic planes.** Complications such as fistula and recurrence of the UD are more common in reoperative cases (Ljungqvist et al., 2007; Zhou et al., 2017).

Key Points: Female Urethral Diverticula: Management

- Concomitant urinary incontinence symptoms should be thoroughly investigated preoperatively, and strong consideration should be given to surgical treatment of bothersome SUI at the time of urethral diverticulectomy.
- Transvaginal excision and urethral reconstruction is the most common approach to the treatment of UD in the female patient.

Surgical Procedures for Sphincteric Incontinence in the Male

Hunter Wessells MD, FACS, Alex J. Vanni MD, FACS

Urinary incontinence (UI), the complaint of any involuntary leakage of urine (Abrams et al., 2002), may be the result of congenital anomalies, injury, genitourinary surgery, and other conditions. The most common cause of sphincteric UI in men is radical prostatectomy (RP), with the primary mechanism being failure to store urine secondary to inadequate resistance of the outlet sphincter. The burden of disease from post-RP UI in the United States remains high because of continued large numbers of RP performed annually, although it may decline because of improvements in surgical technique, reduced use of surgery after the US Preventive Services Task Force recommendations against screening with PSA in 2012 (Halpern et al., 2017), and greater adoption of active surveillance (Chen et al., 2018).

UI significantly compromises health-related quality of life in men (Coyne et al., 2003, 2012) and can be improved by surgical treatment including transurethral bulking agents, bulbar urethral slings, and the artificial urinary sphincter (AUS). These procedures prevent involuntary urinary loss by increasing outlet resistance. **Although bulking agents have been used in the past as first-line treatment for male sphincteric UI, the severity of incontinence and postsurgical scarring in the vesicourethral region post-prostatectomy have made surgical correction first-line treatment for the majority of cases.**

After a number of generations, bulbar urethral slings have been established as effective treatment for male UI. Long-term follow-up is now available for these slings, allowing patients to make informed decisions about treatment, particularly for mild to moderate incontinence. However, **the AUS remains the gold standard for the treatment of UI in males because of its long-term durability and effectiveness across the spectrum of moderate and severe degrees of urine loss.**

The recently published *Incontinence after Prostate Treatment: AUA/SUFU Guideline* (Sandhu et al., 2019) offers the urologic community a systematic literature review with evidence-based guideline statements for the evaluation and management of men with sphincteric urinary incontinence due to prostate surgery. In this chapter, we emphasize relevant information as it pertains to a given topic by referencing Sandhu et al. verbatim.

Classification, Pathophysiology, and Etiology

Urinary continence in the male depends on a compliant and contractile bladder body, functional posterior urethra including the bladder neck and prostate (internal sphincter), and an intact rhabdosphincter (external sphincter). Thus stress urinary incontinence develops only in men with concomitant internal and external sphincter impairment. Internal sphincter incompetence results from pelvic surgery, bladder neck injury, specific sympathetic neuropathic dysfunction, or embryologic disruption. **Incompetence of the external sphincter occurs most frequently after RP** but also can result from pelvic fracture urethral injuries, traumatic and acquired myelopathy, and congenital disorders such as spinal dysraphism, sacral agenesis, and the exstrophy/epispadias complex. **Associated bladder dysfunction including decreased compliance or detrusor overactivity may complicate or confound the diagnosis and management of male UI and requires careful evaluation (see later).**

Male incontinence is rare in the general population, affecting only 5% to 6% of older men (Bortolotti et al., 2000; Wu et al., 2015). The incidence of UI in men parallels the rate of various surgical procedures and urologic conditions listed earlier. **Incontinence after transurethral resection of the prostate (TURP) may reflect persistent bladder overactivity but rarely results from damage to the external sphincter during transurethral resection.** In the classic Veterans Affairs Cooperative Study (Wasson et al., 1995) the rate of de novo UI after transurethral resection of the prostate (TURP) was no different than in the watchful waiting group.

The historical incidence of incontinence after RP varies from 2.5% to 87% (Foote et al., 1991). Wide variation in reported UI rates after RP reflect patient- and surgeon-specific factors as well as methodology of data collection (Flynn and Webster, 2004). Rates of incontinence are higher when calculated from self-report instruments as compared with chart review or physician-recorded outcomes (Carlson and Nitti, 2001; Flynn and Webster, 2004). Progressive improvement in urinary control has been reported to occur up to 2 years after surgery: in one study the percentage of men that used one pad or less after RP was 71%, 87%, 92%, and 98.5% at 3, 6, 12, and 24 months, respectively (Lepor and Kaci, 2004). Nerve-sparing techniques pioneered by Walsh (Eggleston and Walsh, 1985) have been associated with a reduced incidence of postoperative UI (Wei et al., 2000a,b). Although the mechanism of this effect remains debated, sensory and motor pudendal innervation of the rhabdosphincter are generally preserved post-RP; in contrast, autonomic afferent denervation and impaired membranous urethral sensitivity seem to be associated with post-RP UI (Catarin et al., 2008). In systematic review and meta-analysis, nerve sparing techniques have been associated with more rapid return of continence, although not final continence status, after RP (Reeves et al., 2015).

Other proposed mechanisms of post-RP UI besides nerve injury include damage to the external urethral rhabdosphincter, pelvic floor, and bladder neck. A functional and anatomic study (Cameron et al., 2015) comparing continent and incontinent men post-RP found no differences between resting urethral pressure profile (UPP) or length of the pressure zone. However, the peak UPP with Kegel and magnetic resonance imaging (MRI) urethral length were significantly higher in the continent group. Furthermore, the authors found a greater degree of funneling at the bladder neck along with distortion and loss of symmetry of the sphincter area. Modifications to the posterior reconstruction of the rhabdosphincter during RP have been proposed to accelerate return to continence but are not associated with improved long-term continence (Rocco et al., 2012).

Bladder neck stenosis is associated with a reduced continence rate after RP, likely because of secondary surgical intervention (Park et al., 2001). Urethral anastomotic fibrosis (Tuygun et al., 2006) is hypothesized to lead to reduced coaptation of the urethra and sphincter; the endoscopic finding of a “sector defect” or loss of the normal radiating folds of the external sphincter may be the correlate of the earlier-mentioned MRI finding of sphincteric distortion or loss of symmetry.

History and Development of Devices

Devices to control urinary incontinence in men have been described since antiquity (Schultheiss et al., 2000). One of the first modern prosthetic devices to treat incontinence in men was reported by Berry in 1964. This acrylic prosthesis was designed to kink and compress the bulbar urethra, but poor results, pain, and fistula formation led to its abandonment (Engel and Wade, 1969). In 1970 Kaufman reported the first of several procedures to provide continence by compressing the urethra with the Kaufman I procedure. This was modified by incorporating a tetrafluoroethylene mesh tape in the Kaufman II and a silicone-gel–filled hemispheric prosthesis in the Kaufman III, giving a success rate of 70%.

Slings to treat stress UI in men were introduced in 1975 by Kishev, who described the placement of a pliable prosthetic “wad” under the bulbar urethra. Schaeffer then described a bulbourethral sling that used bolsters suspended from the rectus fascia (Clemens et al., 1999a,b; Schaeffer et al., 1998). Another report documented results with a composite graft of polypropylene and porcine skin collagen placed suburethrally (John, 2004). Male bulbourethral slings have continued to evolve with the development of bone screws for stable fixation of synthetic mesh to the inferior pubic ramus (InVance, American Medical Systems, Minnetonka, MN), transobturator fixation (AdVance and AdVance XP, Boston Scientific, formerly AMS, Marlborough, MA) and a combined prepubic and transobturator sling (Virtue, Coloplast, Minneapolis, MN). The bone-anchored sling is no longer commercially available in the United States, which reduces options for complex cases involving failure of a transobturator sling or AUS.

In 1976 Rosen designed the first model of an AUS, but hydraulic failure and fistula formation approached 100%, and this device was abandoned (Fowler and Auld, 1985). Scott presented his initial report with the AMS 721 (American Medical Systems, Minnetonka, MN), noting a 79% success rate (Scott, 1978; Timm et al., 1976). Over the next 10 years, further developments in design of the AUS included automatic cuff closure after cuff decompression (AMS 742), a silicone rubber cuff and a deactivation button (AMS 791, 792) (Scott, 1989), and deactivation button within the control pump (AMS 800). In 1987 the narrow-backed cuff was introduced (Fig. 131.1A), which, by improving pressure transmission from the cuff pressure to the underlying tissue, greatly decreased the incidence of urethral erosion and tissue atrophy (Light and Reynolds, 1992).

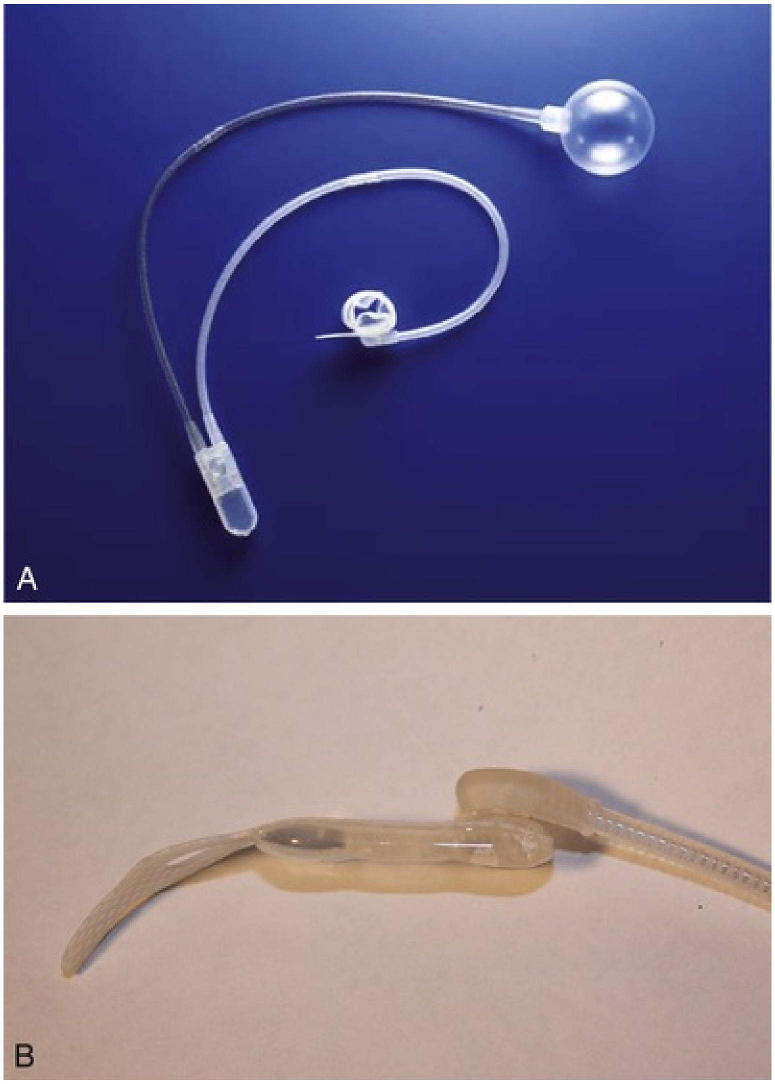

FIG. 131.1 AMS 800 narrow backed artificial urinary sphincter. (A) Cuff, pump, and pressure-regulating balloon. (B) Close-up view of a 3.5-cm cuff. Note the subtle folds of the three-cushion design unique to the 3.5-cm cuff.

The most recent modification of the AMS 800 is the addition of the 3.5-cm cuff to the size options for the device. This has allowed placement in cases with atrophy of the urethra and revision cases necessitating placement of the cuff distally, whereas the urethra is naturally much smaller in diameter. The 3.5-cm cuff has very specific design characteristics (Fig. 131.1B) that were needed to achieve a concentric compression of the urethra in this small diameter (see later). Other strategies developed to address bulbar atrophy include fascial wrapping and transcorporal cuff placement (see later).

Innovations and Emerging Concepts in Device

Design

Although slings and AUS have been available for decades, innovation is necessary because both types of devices have significant limitations and need improvement. The AUS Consensus Group recently developed ideas for several important innovations in sphincter technology that would improve the device (Biardeau et al., 2016). One would be to make the sphincter easier to use so that a patient's manual dexterity was not a prerequisite for implantation. In addition, the device should be simple to deactivate, have cuff pressures that modulate in real-time to the needs of the patient, have system pressures easily modified without the need for revision surgery, and be implantable with minimally invasive techniques. Attempts at overcoming these limitations have progressed by creating an adaptive device that is wirelessly controlled (Lamraoui, 2010; Ruthmann et al., 2010; Valerio et al., 2013). Although a number of these new devices, hydro-mechanical and mechanical, have been studied in humans (Knight et al., 2006; Schiavini et al., 2010; Staerman, 2013), none are approved by the U.S. Food and Drug Administration (FDA), and further refinements are needed to advance beyond current technology.

Adjustable balloon devices may be offered to patients with mild stress urinary incontinence after prostate treatment (Sandhu et al., 2019). The Prostate Adjustable Continence Therapy device (ProACT; Uromedica, Plymouth, MN) consists of two balloons, placed on both sides of the bladder neck to increase outlet resistance. Percutaneous adjustment of the pressure applied to the bladder neck is performed through titanium ports within the scrotum. Hübner and Schlarp showed significantly improved continence as they used this device over time, which stimulated the use of the ProACT device in centers in Europe (Hubner and Schlarp, 2005; Trigo-Rocha et al., 2006). More recent studies show deterioration in success (Venturino et al., 2015). The pivotal trial in the US associated with FDA approval determined that 60% of patients met the primary endpoint and had a greater than 50% reduction in leakage as measured by pad weights (Nash et al., 2018).

Slings are continually developed and studied in the hopes of providing a cure for male UI with the advantage of being easier to implant, not requiring patient hand dexterity, and with fewer potential complications as compared with the AUS. Adjustable slings (e.g., the Adjustable Transobturator Male System [ATOMS], Remeex [not available in the United States]) have been studied in hopes of improving upon existing slings (Advance, Virtue) currently available in the United States. The ATOMS device, available in Canada and Europe, is an adjustable transobturator sling with short-term results demonstrating a 73% dry rate at 2 years' follow-up and may perform better than the Advance sling in radiated patients (Angulo et al., 2017). The ATOMS device involves mesh arms that provide four-point fixation in the pelvis and a silicone cushion in the midportion of the tape. The cushion provides pressure on the ventral aspect of the bulbar urethra and can be adjusted with volume at any time via a port.

The Advance XP was developed in 2010 and has recently undergone clinical trials in Europe as an update to the existing Advance sling (Bauer et al., 2015; Kretschmer et al., 2016). The Advance XP has an updated mesh with integrated tensioning wires and chevron anchors on the mesh arms. A multicenter trial with 3-year follow-up demonstrated outcomes similar to the standard device: post-RP UI cure improved in 66% and 23% of patients respectively; the result did not diminish over time (Bauer et al., 2017).

A number of further refinements in sling technology are needed. Improved efficacy of slings is needed to shift the risk-benefit ratio toward sling in men with moderate to severe incontinence, history of radiation therapy, and those with prior urethral surgery. AUS placement in these men has a significantly greater potential for complications. In addition, if new sling design allowed easier implantation with less potential for variability in placement, it would allow a larger number of urologists to treat patients and potentially improve surgical outcomes. Last, although slings have a lower complication profile compared with AUS, there are postoperative problems related to postoperative urinary retention, perineal/groin pain, and rarely urethral erosion. Sling design should continue to improve upon existing technologies to mitigate these risks to improve the quality of life of our patients.

Mechanisms of Continence With Surgical Devices

Slings have evolved from simple obstructive foreign bodies to sophisticated devices that rely on interaction with the bony pelvis to compress or reposition the male urethra (Fig. 131.2). The mechanism of continence with the bone-anchored sling was thought to be from compression of the urethra, as demonstrated by an increase in fixed resistance of the urethra (Ullrich and Comiter, 2004). Further support for this proposed mechanism was the development of techniques to optimize tensioning of the sling, which also reduce the risk of urinary retention (Comiter, 2002).

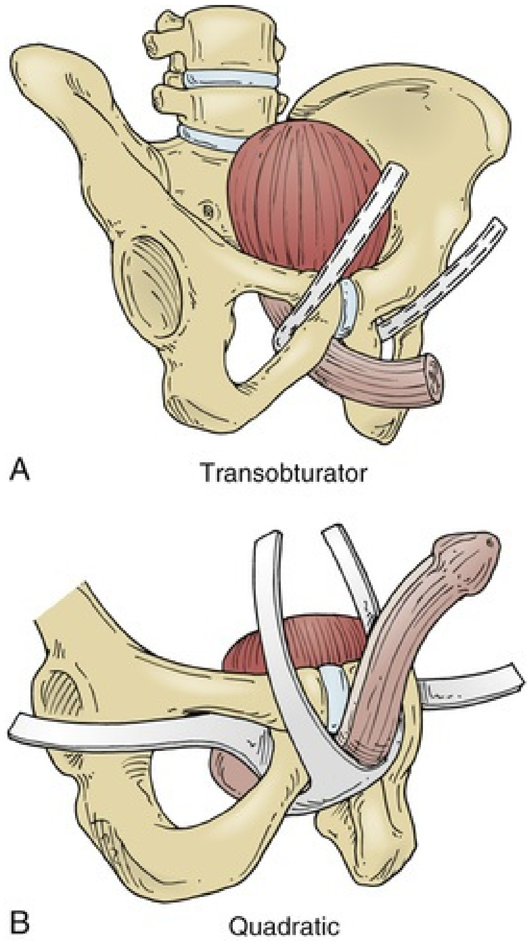

FIG. 131.2 Proposed mechanism of slings. (A) Transobturator. (B) Quadratic fixation.

Transobturator slings are hypothesized to enhance rhabdosphincter function by repositioning and lengthening the membranous urethra without significant compression. Urodynamic studies show an increase in abdominal leak point pressure without other urodynamic evidence of obstruction (Davies et al., 2009; Soljanik et al., 2011). Fluoroscopic studies and magnetic resonance imaging further demonstrate an increase in membranous urethral length and elevation of the bladder neck, posterior bladder wall, and rhabdosphincter (Firrozi and Vasavada, 2009, Soljanik et al., 2013).

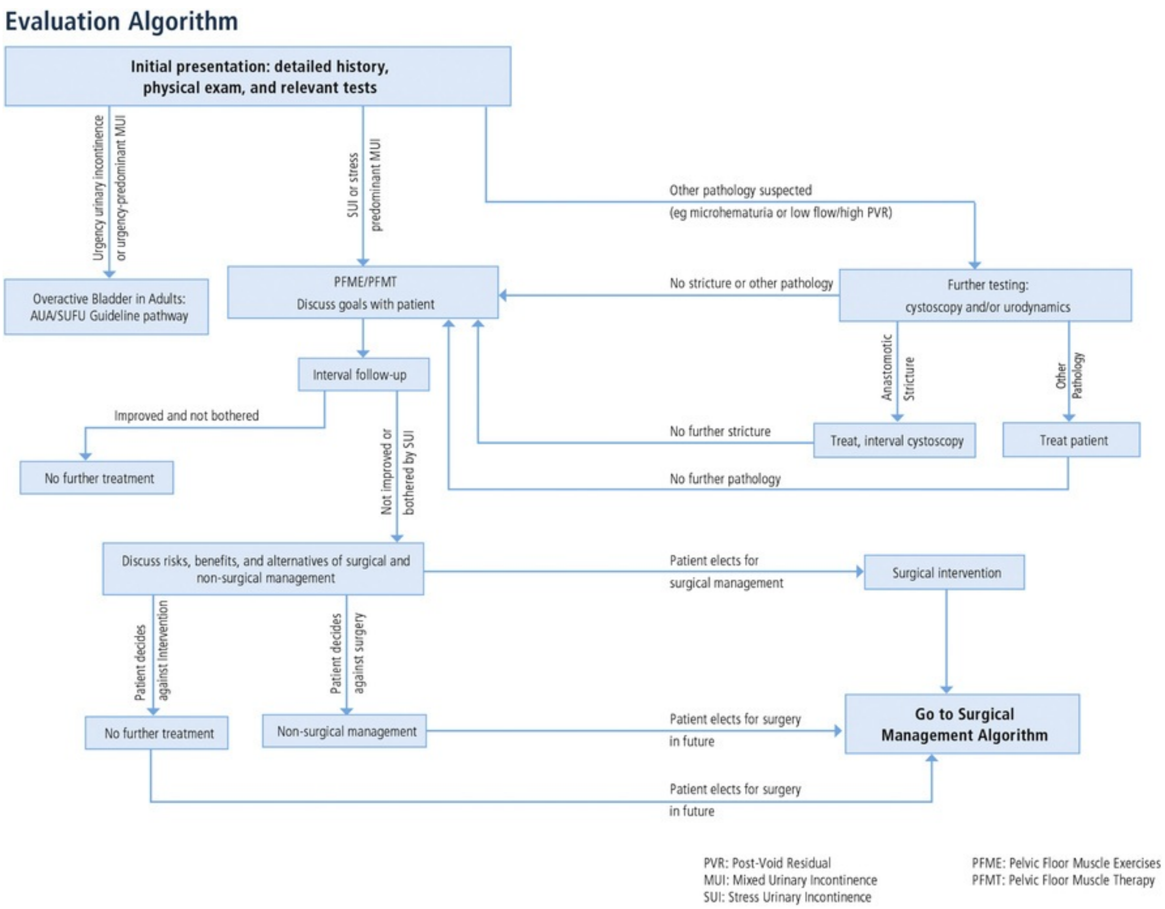
The Virtue sling is a four-armed mesh device (quadratic fixation) that provides a long segment of urethral compression against the urogenital diaphragm and a separate elevation component resulting from the prepubic

and transobturator arms, respectively (Comiter et al., 2012).

The AUS (AMS 800) consists of a fluid-filled cuff placed around the bladder neck or bulbar urethra, which provides a 2-cm zone of circumferential compression. The degree of compression is determined by the compliance of the pressure-regulating balloon (PRB), the pressure of which is selected based on patient tissue characteristics and location of the cuff. **The standard PRB for bulbar AUS, namely 61 to 70 cm H_2O, optimally balances the need for occlusion with the risk for erosion. Lower pressures provide reduced continence rates but may be advisable if risk of erosion is considered excessive.** The degree of occlusion provided by standard 61 to 70 cm H_2O is similar in magnitude to that measured in successful male sling surgery. However, when the cuff is opened, urethral resistance drops to negligible levels, thus allowing men without significant detrusor contractility to empty via straining or Crede. Interestingly, the amount of urethral lengthening achieved with the AdVance male sling, 1.2 cm post-tensioning, is significantly less compared with the 2-cm zone of compression with AUS (Soljanik et al., 2013)**.**

Evaluation and Diagnosis

The initial evaluation of a man with UI requires a detailed history, physical examination, postvoid residual measurement, and urinalysis. AUA/SUFU Guidelines also recommend appropriate diagnostic modalities to categorize type and severity of incontinence and degree of bother (Sandhu et al., 2019). **Cystoscopy and pressure flow urodynamics can be used to evaluate potential bladder neck stenosis, residual sphincteric function, and bladder storage function as indicated.** Fig. 131.3 shows the AUA/SUFU evaluation algorithm.



Evaluation Algorithm
Initial presentation: detailed history, physical exam, and relevant tests
Urgency urinary incontinence or urgency-predominant MUI
SUI or stress predominant MUI
Other pathology suspected (eg microhematuria or low flow/high PVR)
Overactive Bladder in Adults: AUA/SUFU Guideline pathway
PFME/PFMT Discuss goals with patient
No stricture or other pathology
Further testing: cystoscopy and/or urodynamics
Anastomotic Stricture
Other Pathology
Interval follow-up
Improved and not bothered
No further treatment
Not improved or bothered by SUI
No further stricture
Treat, interval cystoscopy
Treat patient
No further pathology
Discuss risks, benefits, and alternatives of surgical and non-surgical management
Patient elects for surgical management
Surgical intervention
Patient decides against intervention
Patient decides against surgery
No further treatment
Non-surgical management
Patient elects for surgery in future
Go to Surgical Management Algorithm
Patient elects for surgery in future
PVR: Post-Void Residual
MUI: Mixed Urinary Incontinence
SUI: Stress Urinary Incontinence
PFME: Pelvic Floor Muscle Exercises
PFMT: Pelvic Floor Muscle Therapy

FIG. 131.3 AUA/SUFU Guideline Evaluation Algorithm for Incontinence after Prostate Treatment. (Reproduced from Sandhu et al., 2019, with permission.)

History

The medical history should focus on the type, degree, and severity of UI; previous surgical procedures; and symptoms of neurologic disease. Specific evaluation of the failed AUS will be considered at the end of this section. **Differentiation between stress and urgency UI is important and can be aided by the voiding diary and pad test, simple inexpensive assessments of urinary incontinence that are recommended before proceeding with invasive testing** (Flynn and Webster, 2004). The 2- to 7-day voiding diary reliably assesses the number of incontinent episodes and may uncover significant urgency and urgency incontinence (Groutz et al., 2000). Self-reported daily pad usage varies considerably with only moderate concordance with urinary incontinence volume (Dylewski et al., 2007). Thus the 24-hour home pad weight test, which objectively measures the magnitude of the incontinence, may be helpful in directing appropriate therapy. However, because the effectiveness of current surgical therapies has not been stratified according to measures of UI severity, the most important current use for the pad test may be as an outcome measure postoperatively.

Patient-Reported Measures

The severity and symptom impact of UI is thought to be an important factor in selection of surgical approach. Patient-reported measures (PRMs) help elucidate the presence and severity of patient symptoms and bother and thus may serve as an important adjunct to the history and physical examination. Validated disease-specific questionnaires such as the UCLA Prostate Cancer Index (PCI) (Litwin et al., 1998) or the Expanded Prostate Cancer Index Composite (Wei et al., 2000a,b) capture symptoms of stress and urgency incontinence in men post-RP, and have traditionally been used in research and as part of retrospective or prospective cohort series. The performance of such instruments in clinical practice and in demonstrating responsiveness to treatment has not, however, been formally assessed. Similarly, the Incontinence Symptom Index and Incontinence Impact Questionnaire-7 have been used to measure AUS outcomes, although neither of these were developed for assessment of male UI (Wingate et al., 2017). Nitti and the SUFU Pad Weight Study Group (Nitti, 2014) developed a questionnaire that uses pad size, number, and degree of wetness to estimate incontinence. It correlates well with actual urine loss and may offer an alternative method that does not require pad weights. Patient-reported outcome measures that closely correlate with pad weight, other symptoms, and patient bother from UI continue to be unmet needs and remain important future directions for the field of male incontinence.

Physical Examination

A complete examination of the abdomen, back, genitalia, perineum, rectum, and neurologic system is essential to identify conditions associated with specific causes of UI. The patient's manual dexterity should be evaluated if considering placement of an AUS. Clinicians should ensure that patients have adequate physical and cognitive abilities to operate the device (Sandhu et al., 2019). The skin should be inspected for signs of breakdown or secondary fungal or bacterial infection, which must be treated before surgery. **Previous surgical incisions should be noted when planning AUS PRB placement. Likewise, inguinal**

hernias should be identified, and if contralateral PRB placement is not possible, concomitant repair is advisable. Scrotal examination will detect pathology that may influence pump placement such as hydrocele, hernias, and scrotal masses. Having the patient perform a Valsalva maneuver in the office may be helpful in demonstrating stress UI.

Laboratory

Urine analysis and culture are required before surgical correction of male UI, and all abnormalities need complete investigation. UTI must be appropriately evaluated and eradicated. Serum creatinine and PSA should be obtained to assess renal function and cancer status post-RP. Renal insufficiency requires careful evaluation before proceeding with surgical intervention.

Cystoscopy

Detection of vesicourethral anastomotic stricture, bladder neck stenosis, and bulbar urethral stricture before planned surgery may be achieved by history or uroflowmetry in most cases (Yurkanin et al., 2001). **Because unrecognized urethral or bladder neck pathology can significantly complicate all surgical approaches, prior to surgical intervention for stress urinary incontinence, cystourethroscopy should be performed to assess for urethral and bladder pathology that may affect outcomes of surgery. A corollary to this is that patients with symptomatic vesicourethral anastomotic stenosis or bladder neck contracture should be treated prior to surgery for incontinence after prostate treatment** (Sandhu et al., 2019). Cystoscopic evaluation of the degree of residual function of the external sphincter may help identify appropriate candidates for transobturator sling procedures (see later and Fig. 131.4). Furthermore, in patients with recurrent incontinence after AUS implantation, cystoscopy may aid in differentiating mechanical failure from other causes such as urethral atrophy. Finally, when an AUS or sling (Harris et al., 2009) has been removed because of infection or erosion, repeat evaluation of the urethra before reimplantation is recommended to identify stricture, diverticulum, and other urethral complications.

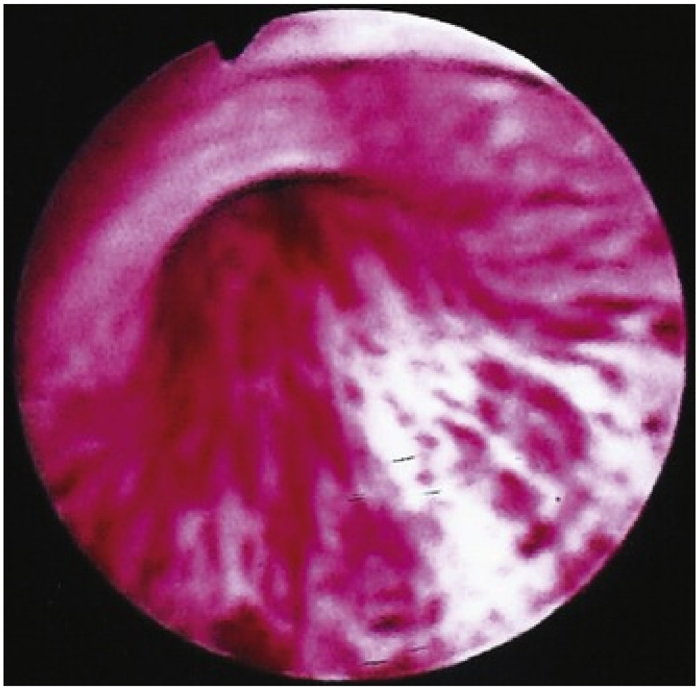


FIG. 131.4 Appearance of external sphincter of a man with post-radical prostatectomy urinary incontinence showing quadrant defect from 9 to 12 o'clock with incomplete circumferential coaptation. Such a patient may not be an ideal candidate for the transobturator sling, which relies on repositioning of a functional external sphincter unit.

Urodynamics

Assessment of bladder capacity, compliance, and contractility is required before considering surgical correction of UI. A careful history and voiding diary may be sufficient to assess the adequacy of bladder function. Noninvasive studies with uroflowmetry and postvoid residual urine volume, when normal, confirm bladder capacity, completeness of bladder emptying, and the absence of bladder neck stenosis. When more comprehensive evaluation is required, however, clinicians may perform urodynamic testing in a patient prior to surgical intervention for stress urinary incontinence in cases where it may facilitate diagnosis or counseling (Sandhu et al., 2019). Intrinsic sphincter deficiency (ISD) will be identified in almost all cases. **Although 40% to 45% of men with UI post-RP have bladder dysfunction, it is the sole cause of incontinence in a very small percentage** (Ficazzola and Nitti, 1998; Leach et al., 1996). Filling cystometry can be difficult in men with severe incontinence, and occlusion of the bladder neck with a balloon catheter may be required to assess compliance and detrusor function. Decreased bladder capacity was a predictor of worse outcomes from male sling surgery in one series (Warner et al., 2012). **Detrusor overactivity, although not a contraindication to surgery for UI if discovered, requires realistic counseling regarding the likelihood of successful outcome.** Patients with urgency urinary incontinence or urgency predominant mixed urinary incontinence should be offered treatment options per the American Urological Association Overactive Bladder guideline (Guideline 10: Clinical Principle). Reduced bladder compliance presents a more serious concern because prolonged storage at high pressures may lead to deteriorating renal function. Notably, such urodynamic findings do not reliably predict worse post-AUS continence (Lai et al., 2009; Trigo-Rocha et al., 2008). This effectiveness in spite of adverse urodynamic findings could portend silent upper tract deterioration. Conversely, **detrusor hypocontractility on pressure flow urodynamics may indicate the need for AUS if adequate detrusor function does not exist to overcome the potential increased outlet resistance of a sling** (Comiter, 2007).

The American Urological Association guidelines on the use of urodynamics for the patient with stress incontinence state at minimum that surgeons considering invasive therapy in patients with stress UI should assess the postvoid residual (PVR) urine volume (Winters et al., 2012). Furthermore, clinicians may perform multi-channel urodynamics in patients with symptoms and physical findings of stress incontinence who are considering invasive, potentially morbid, or irreversible treatments, which include placement of the male sling or AUS.

Evaluation of Persistent Incontinence After Artificial Urinary Sphincter and Sling

The diagnostic evaluation of recurrent UI after AUS must differentiate between inadvertent deactivation, insufficient urethral compression (oversizing of cuff), mechanical failure with fluid loss, cuff erosion, bladder storage failure, urethral or bladder neck atrophy under the cuff, as well as rare causes such as a plugged delay-fill resistor or kinked tubing (Montague et al., 2001). In patients with persistent or recurrent urinary incontinence after artificial urinary sphincter or sling, clinicians should again perform history, physical examination, and/or other investigations to determine the cause of incontinence (Sandhu et al., 2019). The evaluation includes the same general approach described for de novo UI as shown in Figs. 131.3 and 131.5. A history of sudden loss of continence suggests deactivation or mechanical failure. Active cycling of the device excludes inadvertent deactivation. If the pump is deactivated with inadequate fluid to cycle, passive filling can be achieved by squeezing the pump on its lateral edges, pushing on the pump with a cotton-tip applicator opposite the deactivation button, or holding down the button for at least 30 seconds. Fluid loss from the device implies mechanical failure and leak. Plain radiography (for contrast-filled systems) or ultrasonography (for saline-filled systems) of the PRB during cycling can help differentiate fluid loss from cuff atrophy. If the PRB size changes with cycling, and refills passively, mechanical failure is less likely, thus suggesting cuff atrophy (Lorentzen et al., 1987; Taylor and Lebowitz, 1985). Cystoscopy, in addition to excluding erosion, can be used to visualize the cuff during cycling and give insight into the likelihood of atrophy. Urodynamics should be performed when bladder storage failure is suspected, or in cases where it is difficult to determine if incontinence is primarily due to detrusor overactivity. It is axiomatic that in patients with persistent or recurrent stress urinary incontinence after artificial urinary sphincter, revision should be considered (Sandhu et al., 2019).

Evaluation of the patient who underwent prior urethral sling is similar to the evaluation after AUS placement with several caveats. Identifying the type of sling placed (Advance vs. Virtue vs. bone anchored), and the timing of the incontinence are important. In the case of the Advance sling, it is important to determine whether the patient may have loosened the sling in the first 6 weeks postoperatively, whether the incontinence is persistent (ongoing stress UI without improvement), or the result of detrusor overactivity. If patients give a history of improved UI and a loosening of the sling in the first 6 weeks postoperatively, re-exploration is appropriate. The perineum is opened, the arms of the sling lateral to the bulbar urethra are identified, and each arm is cut. The remaining central portion of the sling should be removed from the surface of the corpus spongiosum of the bulbar urethra. This maneuver may require an extensive dissection if the initial sling surgery achieved a significant degree of elevation and invagination of the corpus spongiosum. Another sling can then be placed in the same manner as described later.

In patients with persistent or delayed stress UI after sling placement (i.e., no loosening of the Advance sling in the early postoperative period), evaluation should determine if the incontinence is a result of detrusor overactivity or stress UI. If persistent stress UI (i.e., sling failure) occurs, placement of an AUS is the "gold standard" and can be performed with similar outcomes compared with first-time AUS placement (Lentz et al., 2012; Ziegelmann et al., 2016). Placement of a second Advance sling in cases of late failure of the first sling is feasible in select patients and has been reported with a success rate of 56% at 17.5 months' follow-up (Martinez et al., 2015). We recommend this only in very selected cases when AUS is contraindicated or the patient refuses.

Key Points

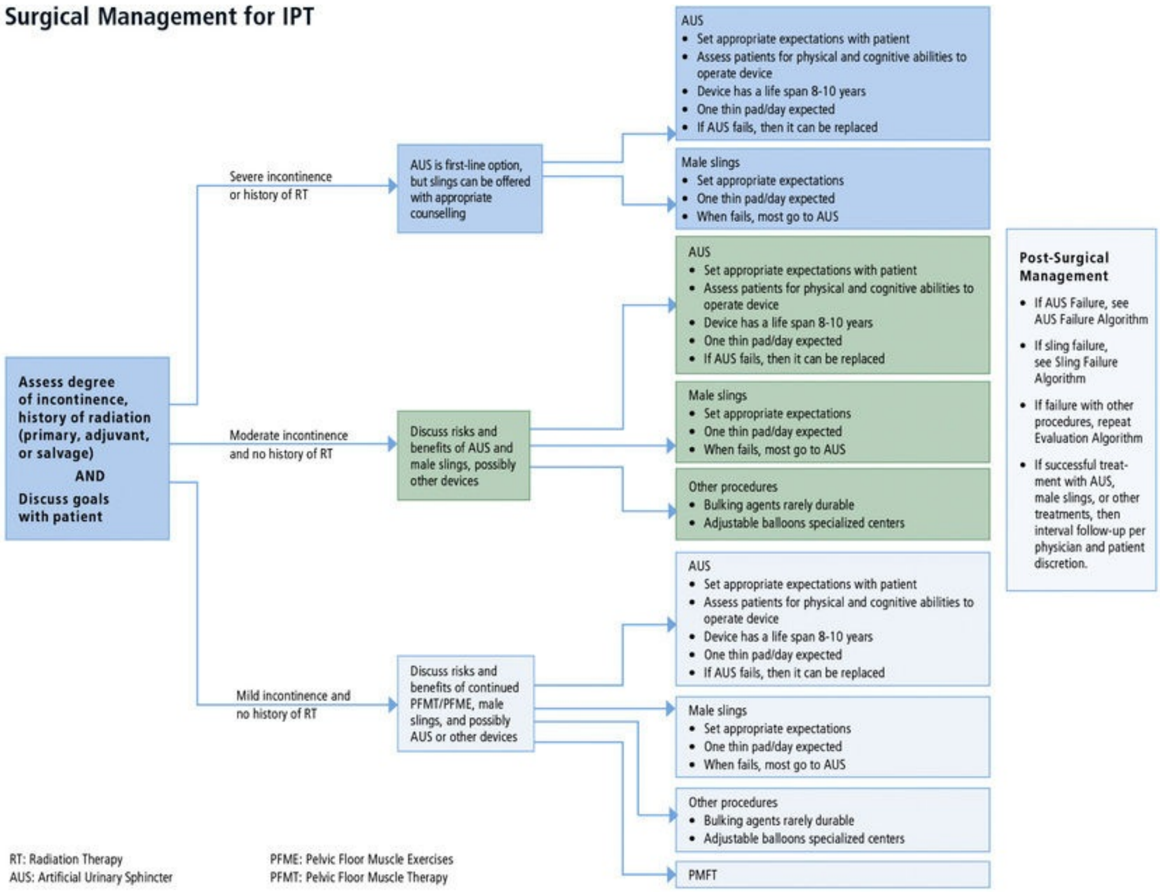
- A careful history and voiding diary characterize the type and severity of urinary incontinence in most men.
- Uroflowmetry and postvoid residual urine volume measurement should be assessed at minimum.
- Suspected outlet obstruction, significant bladder overactivity, or impaired bladder contractility should prompt urodynamic studies.
- Patients with suspected urethral, vesicourethral, or bladder neck pathology should undergo cystoscopy.

- Urinalysis (and culture if indicated) are required before surgical treatment.

Indications for Surgery

Surgical correction of UI is indicated in male patients with irreversible sphincter incompetence and bothersome involuntary leakage of urine. In patients seeking treatment for incontinence after radical prostatectomy, pelvic floor muscle exercises or pelvic floor muscle training should be offered (Sandhu et al., 2019); however, the benefit of extensive or one-to-one pelvic floor muscle training after RP or TURP remains uncertain (Anderson et al., 2015; Campbell et al., 2012). Because progressive improvement in continence occurs after RP, some authors recommend a 1-year observation period (Flynn and Webster, 2004; Peyromaure et al., 2002). However, in patients with bothersome stress urinary incontinence after prostate treatment, surgery may be considered as early as six months if incontinence is not improving despite conservative therapy (Sandhu et al., 2019). Patients with incontinence after prostate treatment should be counseled that efficacy is low and cure is rare with urethral bulking agents (Abrams et al., 2009; Herschorn et al., 2010; Kuznetsov et al., 2000; Montague and Angermeier, 2000; Sandhu et al., 2019.)**. Thus AUS and slings should be considered as first-line surgical therapy for sphincteric incontinence in most men, although a trial of a bulking agent may be appropriate in cases of neurogenic male stress UI.**

Once the diagnostic evaluation has been completed (see Fig. 131.3), patients should be informed of management options for their incontinence, including surgical and non-surgical options (see Fig. 131.6). Physicians should discuss risk, benefits, and expectations of different treatments using the shared decision-making model (Sandhu et al., 2019). **Factors to consider include the severity of UI and associated bother; patient characteristics including body mass index, prior surgical procedures including urethroplasty, primary or adjuvant radiation therapy, bladder function, and cystoscopic findings; manual dexterity and cognitive function; efficacy of the various implants; long-term risk of complications and reoperation; and patient preference. Absolute contraindications to surgical correction of male UI are few and include bladder disorders that jeopardize renal function such as diminished vesical compliance and vesicoureteral reflux at low intravesical pressure. Inadequate tissue integrity at the bladder neck or urethra to accommodate a sling or AUS may require bladder neck closure or urinary diversion.** A urinary diversion can be considered in patients who are unable to obtain long-term quality of life after incontinence after prostate treatment and who are appropriately motivated and counseled (Sandhu et al., 2019). **In addition, urinary tract abnormalities that require future transurethral management, such as bladder cancer or refractory vesicourethral anastomotic strictures, should be considered relative contraindications to surgery.** In such cases, an AUS or sling procedure could impair transurethral access, and repeated instrumentation may put the devices at risk for infection or erosion. Although metastatic prostate cancer is not a contraindication to surgical correction of UI, improvements in quality of life must be balanced against performance status and life expectancy.



Surgical Management for IPT
Assess degree of incontinence, history of radiation (primary, adjuvant, or salvage) AND Discuss goals with patient
Severe incontinence or history of RT
AUS is first-line option, but slings can be offered with appropriate counselling
AUS
Set appropriate expectations with patient
Assess patients for physical and cognitive abilities to operate device
Device has a life span 8-10 years
One thin pad/day expected
If AUS fails, then it can be replaced
Male slings
Set appropriate expectations
One thin pad/day expected
When fails, most go to AUS
Moderate incontinence and no history of RT
Discuss risks and benefits of AUS and male slings, possibly other devices
AUS
Set appropriate expectations with patient
Assess patients for physical and cognitive abilities to operate device
Device has a life span 8-10 years
One thin pad/day expected
If AUS fails, then it can be replaced
Male slings

FIG. 131.6 AUA/SUFU Algorithm for Surgical Management. (Reproduced from Sandhu et al., 2019, with permission.)

Artificial urinary sphincter should be considered for patients with bothersome stress urinary incontinence after prostate treatment (Sandhu et al., 2019). **It AUS remains the established device for treatment of moderate to severe UI, supported by numerous publications documenting its benefits.** Advantages include reproducible and reliable outcomes, ability of patients to empty the bladder without detrusor contraction, and proven efficacy after pelvic irradiation. A national study using validated questions from the UCLA PCI provides useful data on AUS results (Dalkin et al., 2003). Few men after AUS implantation have severe degrees of incontinence (9%), but many continue to use pads and report a moderately high urinary bother. There is evidence that men who are completely dry after RP have significantly better health-related quality of life compared with those who wear one pad daily (Cooperberg et al., 2003). Whether this is also the case after AUS remains unknown. **Long-term durability of the AUS is well established, although a revision rate of 16% and 28% at 2 and 5 years, respectively, highlights the limitations of the devices** (Dalkin et al., 2003) and is consistent with other single institution series in which 72% to 75% had the original sphincter in place and functioning at or beyond 5 years (Elliott and Barrett, 1998; Lai et al., 2007).

Perineal slings have been established as an alternative to AUS and should be considered as treatment options for mild to moderate stress urinary incontinence (Sandhu et al., 2019). A transobturator sling introduced by AMS (AdVance) in 2007 has been shown to be effective in short-term to intermediate-term follow-up of well-characterized case series. In selected populations, approximately 75% of patients are cured or significantly improved, with results persisting at 12 to 36 months (Kowalik et al., 2015). Thus **male sling procedures represent an established part of the surgical armamentarium for UI by providing an alternative to AUS for mild to moderate UI.**

AUA/SUFU Guidelines provide a moderate recommendation based on lower level evidence that "male slings should not be routinely performed in patients with severe stress incontinence" (Sandhu et al., 2019). Slings can be seen as alternatives for correction of more severe UI in those who refuse AUS from fear of infection, erosion, or mechanical failure as well as those with limited physical or cognitive capacity. In two small case series of patients with neurogenic stress incontinence, 28% to 65% of patients with UI improved (Groen et al., 2012; Vainrib et al., 2015). Although slings have a lower complication profile, one study showed that 30% of patients needed the sling removed for either infection or perineal wound breakdown (Vainrib et al., 2015). **The trade-off between risk and efficacy must be considered, with most authors recommending AUS for more severe UI. For mild UI, bulbar sling procedures become a preferred alternative, whereas AUS may represent therapeutic overkill. Thus the transobturator slings should be primarily used in cases with mild to**

moderate incontinence, which can be defined as a 24-hour pad weight of less than 150 g for mild UI (Flynn and Webster, 2004) **and less than 400 g for moderate UI** (Collada Serra et al., 2013; Fischer et al., 2007). In men with stress urinary incontinence after primary, adjuvant, or salvage radiotherapy who are seeking surgical management, artificial urinary sphincter is preferred over male slings or adjustable balloons (Sandhu et al., 2019). **A sling procedure should be offered with caution to those with prior radiation therapy or urethral erosion, because the degree of urine loss that exists in this group usually exceeds the limits of the procedure** (Castle et al., 2005; Dikranian et al., 2004; Giberti et al., 2009; Schaeffer et al., 1998; Torrey et al., 2013). One reason for the lower efficacy in these patients may be the lack of appropriate tissue elasticity for deformation/elongation/compression of the rhabdosphincter apparatus.

When deciding between the two devices (AUS vs. sling) men follow surgeon recommendations. However, when given the choice, men most often choose the sling to avoid the perceived risks of mechanical malfunction, revision surgeries, and device-associated problems (Kumar et al., 2009). This tendency may lead to a higher rate of failure with slings. In light of these choices made by patients and clinicians, a subset of men is predicted to require reoperation after placement of a transobturator male sling, because of inadequate treatment of incontinence.

Key Points

- Surgical intervention is indicated for stress urinary incontinence resulting from ISD that fails to improve with conservative management.
- Implant selection depends on the severity of UI; prior surgical procedures; bladder function; cystoscopic findings; manual dexterity and cognitive function; long-term risk of complications and reoperation; and patient preference.
- Slings should only be used very selectively in cases of radiation and severe gravitational UI.
- AUS should not be used in cases of poor manual dexterity, cognitive disability, poor urethral tissue integrity, or severely reduced bladder compliance.

Technique of Device Implantation

Operative Preparation

The entire operative site is shaved and ideally should incorporate chlorhexidine-alcohol skin preparation, including the lower abdomen, genitals, and perineum (Darouiche et al., 2010; Yeung et al., 2013). Surgery is conducted under general or spinal anesthesia with the patient in the low lithotomy position. **Intravenous antibiotics including an aminoglycoside (5 mg/kg) and a first- or second-generation cephalosporin or vancomycin are administered within 60 minutes before skin incision according to the American Urological Association (AUA) Best Practice Statement on antimicrobial prophylaxis** (Wolf et al., 2008). A chlorhexidine scrub for 10 minutes followed by Iodine Povacrylex (0.7% available Iodine) and isopropyl alcohol, 74% w/w (DuraPrep) was shown in one recent study to reduce postpreparation bacterial skin culture rates compared with povidone-iodine, although clinical implant infection rates were similar between groups (Yeung et al., 2013). The patient is then carefully draped; a urethral catheter may be placed to drain the bladder and facilitate identification and dissection of the urethra.

Artificial Urinary Sphincter

In the patient who selects artificial urinary sphincter, a single cuff perineal approach is preferred (Sandhu et al., 2019). The aim is to place the cuff as proximal on the bulbar urethra as possible, proximal to the fusion of the two corporal bodies (Fig. 131.7A). This location allows safe circumferential dissection of the urethra, provides protection of the cuff from opening while sitting, and exposes the largest diameter of corpus spongiosum for placement of the cuff. A **trans-scrotal approach popularized by Wilson et al.** (2003) **demonstrated suboptimal results for the control of incontinence, and required modification** (see later).

cavernosum. (D) Dissection at interface between spongiosum and left crus of the cavernosum. *AUS,* Artificial urinary sphincter.

After incision of the skin, Colles fascia, and bulbospongiosus muscle, Buck fascia is incised as it reflects off the bulbar urethra onto the diverging corporal bodies (Fig. 131.7B through D). A 2-cm wide tunnel is created under direct vision using sharp dissection dorsal to Buck fascia over the roof of the urethra. A right-angle clamp is then passed through this tunnel. Blunt spreading dissection is discouraged in this area because it risks injury to the urethra, especially in reoperative cases. **The circumference of the urethra is measured around the corpus spongiosum to guide selection of cuff size, most commonly 4.0 or 4.5 cm.** Surgeons should develop a standardized approach to cuff sizing. Whether to remove the urethral catheter before measurement (our choice) is less important than consistently applying a method and developing familiarity with the fit of the cuff compared with the tape measurement. As a rule of thumb, the actual cuff is slightly tighter than the tape measure. If the cuff size is obviously incorrect, the appropriate next size should be selected. Although some authors advocate selecting a cuff size 0.5 to 1 cm smaller than the measured circumference of the urethra to compensate for postoperative sub-cuff atrophy of the spongiosum, a recent study suggests that cuffs that are *less tight* have better continence outcomes (Rothschild et al., 2014). The best test of cuff fit is the visual and endoscopic appearance after it has been placed around the urethra (Fig. 131.8A and B). The tubing from the AUS cuff is passed through the overlying bulbospongiosus muscle into the deep perineal space beneath Colles fascia.

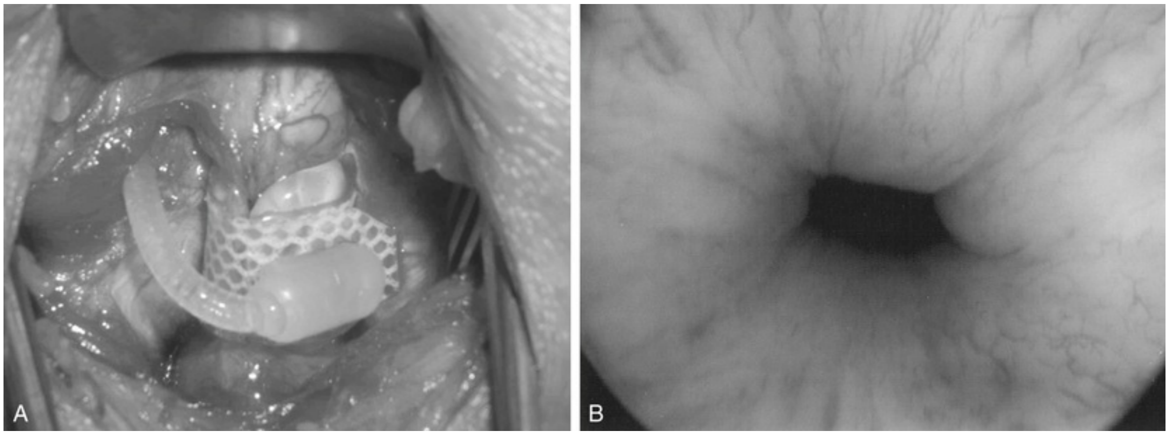

FIG. 131.8 Appropriate appearance of cuff. (A) Perineal placement encircling the bulbar urethra. (B) Endoscopic appearance with cuff activated.

The cuffs are available in various sizes, starting at 3.5 cm and range up to 11 cm (3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 6.5, 7.0, 7.5, 8.0, 9.0, 10.0, 11.0). The larger sizes are reserved for bladder neck implantation. The 3.5-cm cuff allows the surgeon to further downsize devices to obtain better urethral coaptation in patients with significant urethral atrophy from prior AUS placement and those needing very distal placement of cuffs because of multiple revisions. Use of the 3.5-cm size has resulted in an increased risk of erosion in patients with a prior history of radiation therapy (Brant et al., 2014; Simhan et al., 2015). Patients with radiation therapy or other adverse risk factors and significant urethral atrophy should be considered for transcorporal placement rather than a 3.5-cm cuff (see later).

Pressure-Regulating Balloon

The placement of the PRB may be achieved through a scrotal, perineal, or abdominal incision, depending on prior surgical incisions, body habitus, and surgeon preference. Implanters should be familiar with each approach. For abdominal placement, a horizontal lower quadrant incision is made in the abdomen ipsilateral to pump placement. The rectus or external oblique fascia is incised, allowing the surgeon to split the underlying muscle and access the preperitoneal or intraperitoneal space. Digital dissection creates the space required for the PRB, which is small. **We place a 61- to 70-cm H_2O PRB in bulbar AUS and reserve the 71 to 80 cm H_2O PRB for bladder neck cuff placement.** The abdominal wall fascia is closed around the tubing.

Alternatively, the PRB can be placed via the external inguinal ring, using techniques adapted from penile implant surgery. With use of either a scrotal or perineal incision, the external ring is identified and used to provide access to the retropubic space by penetrating through the floor of the inguinal canal with a finger tip or instrument. No sutures are required because the transversalis fascia provides a natural barrier to PRB extrusion. Contraindications to this approach include mesh hernia repairs, radical cystectomy, and other extensive abdominal surgery. In such cases, the abdominal approach reduces the risk of inadvertent bladder or intestinal injury.

The PRB is filled with 23 mL of sterile normal saline or contrast material, unless a bladder neck cuff is used, which requires additional fluid volume according to manufacturer instructions. Filling solutions include 0.9% normal saline, Cysto-Conray 60 cc of contrast diluted with 15 cc of sterile water, or

Hypaque 25% 50 cc contrast diluted with 60 cc of sterile water. To provide an isotonic solution, contrast solutions should always be diluted with sterile water. Contrast media are contraindicated if the patient has an iodine or contrast allergy.

Control Pump Placement

The pump assembly is placed into the anterior scrotum from the inguinal, scrotal, or perineal incision. When the PRB has been placed abdominally, dissection proceeds inferiorly to the scrotum above the abdominal wall fascia accessing the anterior scrotum deep to Scarpa fascia. A finger placed outside the dependent portion of the scrotum then invaginates this skin upward into the inguinal incision, allowing the fascial layers to be stripped off the dartos layer with an instrument, creating a small pocket for the pump (Fig. 131.9). The pump is then placed into that position. For the single-incision approaches, a small subdartos pouch is created directly from the scrotal or perineal incision, orienting the pump accordingly toward the foot (scrotal) or head (perineal), respectively.

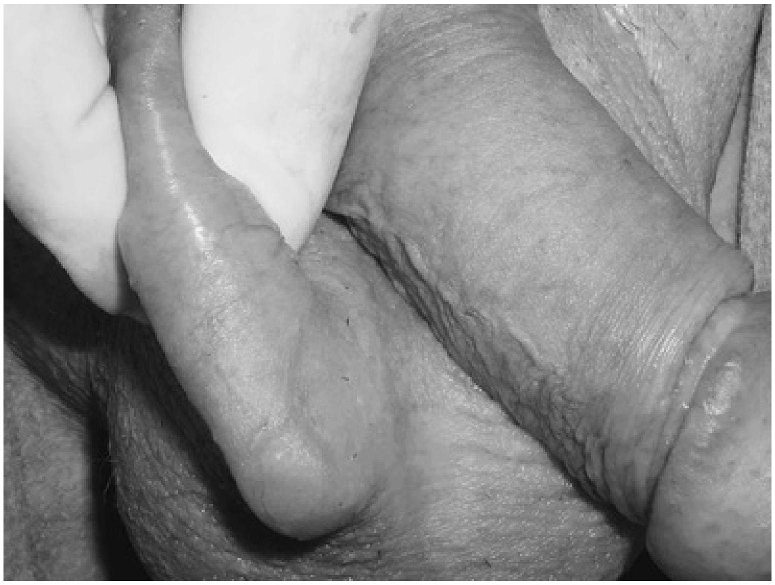

FIG. 131.9 Placement of the pump beneath the skin in a subdartos pocket.

Making the Connections

Connections are typically made in the abdominal incision, when used, protecting the connections from excess wear and allowing easy exploration at a later date. **The quick connectors supplied by the manufacturer provide excellent, secure, and watertight connections for newly implanted devices. However, they are not recommended for revision surgeries because a biofilm on the tubing interferes with watertight connection.** Therefore one must use hand-tie connectors in revision cases in which the entire device is not being replaced.

After the connections are complete, the device is cycled several times through the activation and deactivation states. We verify adequate coaptation of the urethra via urethroscopy. The closed cuff should cause slight blanching of the urethral tissue, indicating adequate urethral coaptation, filling and connection of the device (see Fig. 131.8B). Conversely, the deactivated cuff should cause minimal coaptation. If coaptation is deemed excessive in this circumstance, replacement with a larger diameter cuff should be considered.

Tandem Cuff Artificial Urinary Sphincter

Up to 11% of men may have significant incontinence after single-cuff AUS placement, despite significant improvements in AMS 800 design and implantation techniques (Montague and Angermeier, 2000). In such patients, when the cause of persistent UI is incomplete urethral occlusion, the addition of a second cuff around the bulbar urethra (Fig. 131.10A and C) can yield satisfactory continence (Brito et al., 1993; DiMarco and Elliott, 2003; Kabalin, 1996; O'Connor et al., 2003). **Indiscriminate use of the tandem cuff approach as first-line surgical treatment should be tempered by higher rates of erosion associated with the distal cuff in several series** (Bell and Mulcahy, 2000; Kowalczyk et al., 1996a,b)**. In addition, many patients undergoing AUS placement require subsequent AUS revision surgery, and tandem cuff placement limits available urethral locations for future cuff placement**.

FIG. 131.10 Diagram of the artificial urinary sphincter implantation techniques including perineal (A), scrotal (B), tandem (C), and transcorporal (D) approaches. Note the incorporation of the ventral tunica albuginea with the corpus spongiosum in the transcorporeal approach.

Placement of the second cuff can be accomplished via the perineal incision. After circumferential dissection around the distal bulbar urethra, at least 1.5 to 2 cm distal to the primary cuff, a new cuff is placed. **Connection to the existing device requires division of the existing cuff tubing and use of a metal** Y-

connector. An additional 3 mL of fluid must be added to the system. When a new cuff is added to an existing system, the tubing must be connected with hand ties as described earlier. The entire device is left deactivated for 6 weeks postoperatively.

Transcorporal Artificial Urinary Sphincter Cuff

The transcorporal placement of the AUS provides another approach to difficult initial or revision surgery (Guralnick et al., 2002). Placing a transcorporal cuff after prior erosion or urethroplasty should be performed at a different location along the bulbar urethra (Biardeau et al., 2016). Rather than dissecting between the corpus spongiosum and the ventral surface of the corpora cavernosa, this technique leaves the ventral tunica albuginea attached to the dorsum of the spongiosum (see Fig. 131.10D). Parallel longitudinal incisions in the tunica albuginea of the corpora cavernosa, near the interface with the corpus spongiosum, allows the plane of dissection to pass through the septum of the corpora from one side to the other (Fig. 131.11A). The lateral edges of the tunica albuginea are imbricated *behind* the urethra before cuff measurement (see Fig. 131.11B). Closing the tunica albuginea this way reduces the risk of surgical site hematoma. Although there is a theoretical risk of impaired sexual function with the transcorporal approach, two small series have demonstrated that erectile function can be preserved in most sexually active men (Smith et al., 2013; Wiedemann et al., 2013). An operative video in the AUA video series details the technique.

Advantages of the transcorporal approach include reduced risk of urethral injury during reoperation after prior erosion, urethra injury, urethroplasty, or rectourethral fistula repair; better cuff fit because of the increased bulk of the urethra; and *potential* reduction in erosion risk in high-risk patients (see Fig. 131.10). The technique is particularly useful when proximal cuff atrophy occurs leaving a small caliber urethra (e.g., 3.5-cm cuff or smaller) available distally. A prospective study evaluating urethral erosion with AUS found that men with prior radiation therapy, prior AUS erosion, and 3.5-cm cuff had an increased risk of cuff erosion (Brant et al., 2014). Patients undergoing transcorporal AUS are more likely to have transient urinary retention requiring suprapubic cystostomy placement (Smith et al., 2013). Transcorporal placement may yield AUS continence results similar to those in Table 131.1. Rates of cure or improvement in UI in patients undergoing transcorporal placement in high risk patients has been reported between 76% and 84%, without urethral erosion (Guralnick et al., 2002; Wiedemann et al., 2013). Literature on the effectiveness of this approach remains sparse with most series reporting a combination of both the standard and transcorporal techniques (Hoy and Rourke 2015; Sathianathen et al., 2014; Smith et al., 2013).

Trans-Scrotal Artificial Urinary Sphincter

Wilson et al. (2003) described a technique in which all components of the AUS are placed through a transverse scrotal incision. Originally developed for reoperative surgery because of urethral atrophy, it allowed placement of a more distal cuff in tandem or with the transcorporal technique (see Fig. 131.10B). Although the initial report was favorable in terms of continence outcomes, several reports suggest that the trans-scrotal technique yields inferior continence results (Henry et al., 2008; Stone et al., 2003). One possible explanation is that it does not allow equivalent placement of the cuff around the proximal, larger diameter bulbar urethra when compared with the perineal approach. Corroborative evidence comes from data on implanted cuff size. In a large series, 267 of the 272 perineal cuffs measured 4.5 cm, whereas the remaining cuffs were 5.0 cm (Elliott and Barrett, 1998). Conversely, in the trans-scrotal series, 32 of the 37 cuffs measured 4.0 cm and the remaining cuffs were 4.5 cm (Wilson et al., 2003). A modified version of the trans-scrotal approach, using enhanced exposure (Wilson et al., 2010), has allowed the use of larger cuff sizes around the proximal bulbar urethra and may address the concerns raised in the literature. The authors prefer the more proximal location achieved with perineal cuff placement, leaving the more distal implantation sites available for subsequent revision surgeries.

Bladder Neck Artificial Urinary Sphincter

Bladder neck AUS remains an optional, more invasive, and technically challenging method of cuff placement in those men with sphincteric UI in whom the prostate is without external surgical or traumatic disruption. Thus for causes of myelomeningocele and other neuropathic disorders it should be considered as an alternative to bulbar AUS (Herndon et al., 2003)**. Its use is contraindicated after RP.** Advantages include lower likelihood of erosion and cuff atrophy. Placement of the cuff is more complex, requiring a lower abdominal incision, exposure of the bladder base, and circumferential dissection of the vesicoprostatic junction. Opening the endopelvic fascia helps to develop of the plane of dissection; a catheter placed in the urethra and another in the rectum helps in identifying these structures. If necessary, cystotomy with placement of a finger in the lumen of the bladder neck may also assist the dissection. Similarly, the procedure can also be completely robotic, allowing dissection of the posterior plane between the bladder and seminal vesicles under direct vision and potentially avoiding the need for a lower abdominal incision (Yates et al., 2013). The bladder neck in adults requires a much larger cuff implant (usually 8 cm or greater), higher PRB pressure (usually 71–80 cm H_2O), and a larger fluid volume in the system. Manufacturer packaging includes details relevant to implantation, including determination of the extra fluid required in the system. In children, cuff and PRB characteristics may have to be altered significantly (Ruiz et al., 2006).

Key Points

- Standard implantation of the bulbar AUS places the cuff around the corpus spongiosum proximal to the convergence of the corporal bodies.
- Pressure-regulating balloon of 61 to 70 cm H_2O is advised for bulbar urethral cuffs. Placement may be via abdominal, scrotal, or perineal approach.
- Postoperative deactivation of the cuff for 4 to 6 weeks is essential for proper healing without erosion.
- Prolonged urinary retention requires suprapubic cystostomy drainage.
- Revision surgery for nonmechanical causes may require transcorporal cuff placement or other modifications such as using 3.5-cm or tandem cuff.

Transobturator Bulbourethral Sling

Rehder and Gozzi (2007) described a male transobturator sling that provides an alternative surgical technique for suburethral placement. Its use has been primarily for post-RP male UI, although indications have been broadened to include UI after TURP and laser enucleation (Barnard et al., 2014; Kretschmer et al., 2016) because the surgical management of stress urinary incontinence after treatment of benign prostatic hyperplasia is the same as that for patients after radical prostatectomy (Sandhu et al., 2019). **Transobturator male slings are designed to reposition and lengthen the membranous urethra.** After exposing the corpus spongiosum in a manner identical to the AUS described earlier, freeing the bulbospongiosus muscle off the spongiosum at a convenient starting point, the corpus spongiosum is dissected along its ventral surface proximally to the level of the perineal body, which is marked for later sling positioning and then taken down to release the most proximal bulb. The corpus spongiosum is thus released from the bulbospongiosus muscle to allow appropriate repositioning with tensioning of the sling. The next step is to develop the space between the corpus spongiosum and diverging corpus cavernosum on each side. It is important that the surgeon can feel the inferior pubic ramus *behind* each crus so that the trochar can be received safely onto the fingertip as it comes around.

Using the inferior margin of the adductor longus muscle as a landmark, a small stab wound is made approximately 1 fingerbreadth below the muscle on each side, in the groin crease. A spinal needle locates the obturator foramen immediately lateral to the pubic ramus. Then, using an outside-inside direction, the surgeon inserts the appropriate left- or right-sided helical passing device from the thigh through the obturator foramen and out of the perineal wound medial to the ipsilateral corporal body. The surgeon will feel two "pops" as the trochar passes through the various layers before turning the trochar. The trochar should be brought out as close as possible to the superior aspect of the angle formed by the corpus spongiosum medially and the ipsilateral inferior pubic ramus laterally. Once this has been completed, the polypropylene mesh is loosely positioned in the perineum, attached to the passing device on each side in turn, and pulled out of the obturator foramen to the medial thigh without tension. The proximal aspect of the sling is positioned at the pre-marked area of the distal aspect of the perineal body (Fig. 131.12A). **The sling is then fixed to the corpus spongiosum with 4 to 6 permanent or absorbable sutures. Once fixed in place, the arms of the sling are then steadily and equally pulled up to tension the device. With tensioning, the perineal body and proximal bulbar urethra should move proximally and cephalad 3 to 4 cm to achieve appropriate positioning** (Fig. 131.12B). The maneuver can also be performed during cystoscopic visualization of the external sphincter region, to verify the cephalad repositioning of the membranous urethra (Fig. 131.12C and D). Once in position, final tensioning is achieved after removing the plastic covering of the sling arms. The tail ends of the sling are tunneled by pulling the device ends into the main perineal incision without trimming excess length. The perineal incision is closed in layers, including the bulbospongiosus muscle, Colles fascia, and skin. Overnight catheter drainage is usually sufficient for decompression of the bladder.

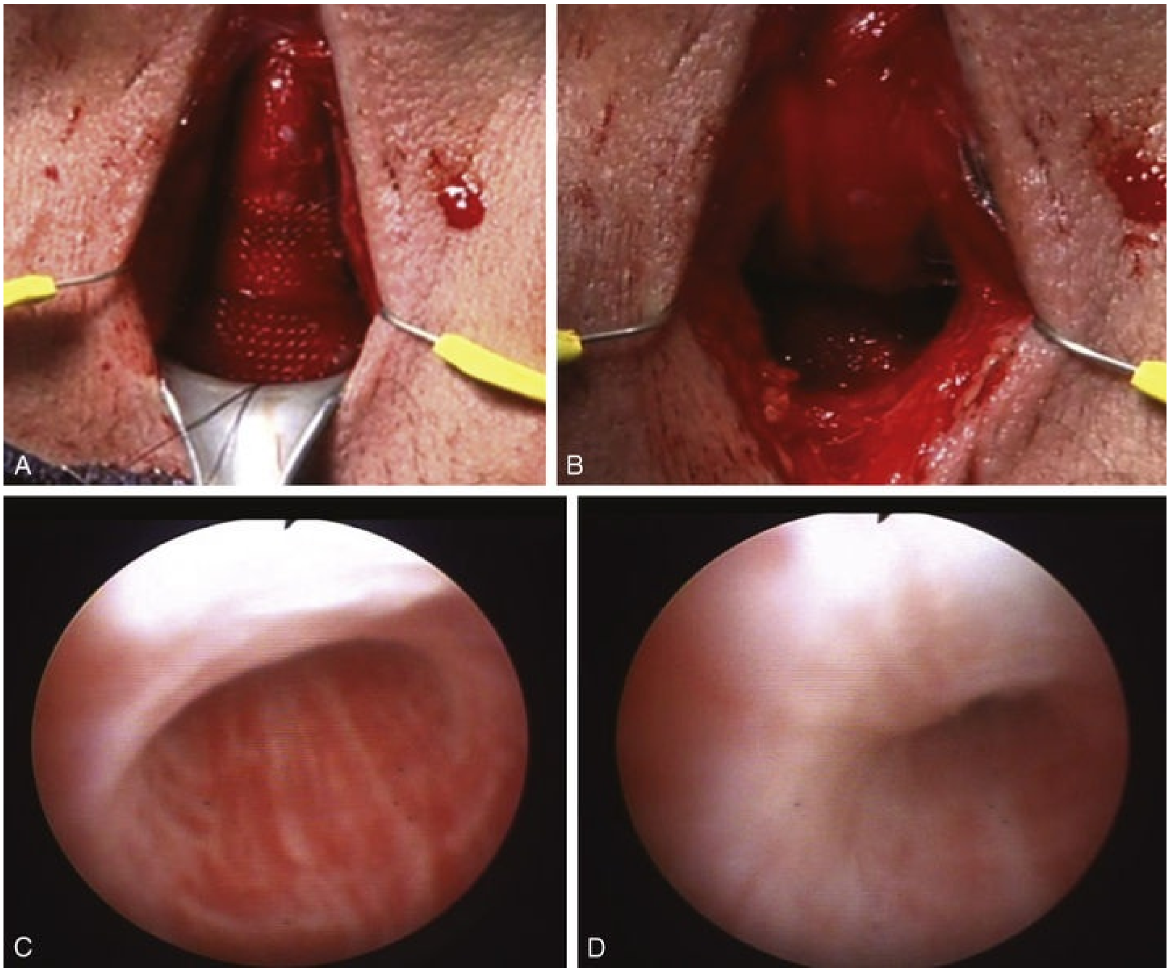

FIG. 131.12 Transobturator sling. (A) Perineal appearance of sling in place on corpus spongiosum before tensioning. (B) Perineal appearance of sling after tensioning. (C) Endoscopic appearance before tensioning. (D) Endoscopic appearance after tensioning.

Four-Arm Sling

A four-arm sling with two lateral strips for transobturator urethral elevation in addition to two prepubic arms designed to provide concomitant compression (see Fig. 131.2) yielded acceptable results (Comiter, 2007) leading to FDA approval. The device offers quadratic fixation and is marketed by Coloplast as Virtue (Comiter et al., 2012). A subsequent report emphasized the importance of sling fixation prepubically (Comiter et al., 2014). A small prospective cohort study of patients with mild UI showed significant improvement with durable outcomes at 3 years (Ferro et al., 2017). Its role in the treatment armamentarium has not been fully defined, but because of its compressive mechanism, the device may potentially be used across a range of UI severity and a wider spectrum of causes in addition to RP.

Key Points

- Male bulbar urethral slings are indicated in men with mild to moderate sphincteric UI, intact bladder contractility, and well-vascularized, nonradiated urethral anatomy.
- Transobturator slings reposition and elongate the membranous urethra and depend on the intact external sphincter.
- Quadratic fixation provides an alternative to the two-arm devices with limited data on efficacy and durability.

Artificial Urinary Sphincter Complications

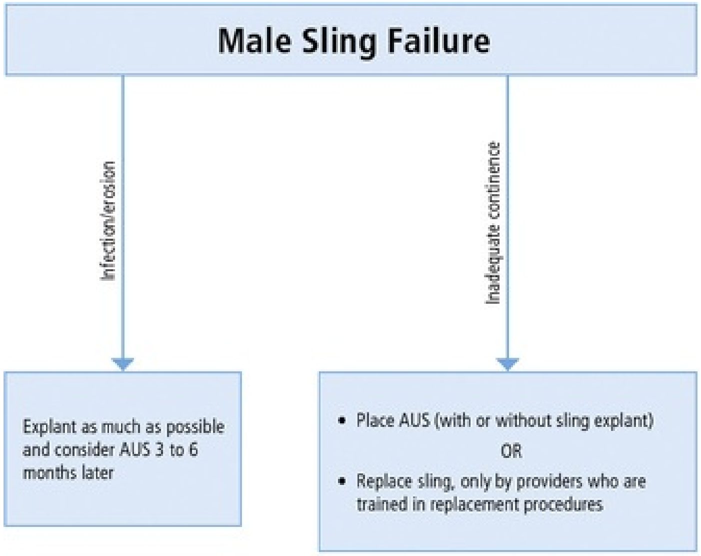
Urinary Retention

Urinary retention after AUS is rare but more frequent with transcorporal and 3.5-cm cuffs compared with larger cuffs (Smith et al., 2013). Retention in the immediate postoperative period should be managed by transurethral bladder drainage with a small (10-Fr or 12-Fr) catheter for 24 to 48 hours. Cuff deactivation must be confirmed before catheterization. **If the patient fails a voiding trial at 48 hours, suprapubic cystostomy drainage is recommended to reduce the risk of urethral erosion.** Ultrasound or fluoroscopic guidance is recommended to prevent puncture or potential contamination of the PRB. Retention persisting beyond several weeks implies undersizing of the cuff; in such cases reoperation and cuff replacement may be required. Correlation with preoperative urodynamic findings is advised in such case. Late-onset urinary retention mandates endoscopic and urodynamic evaluation to rule out proximal urethral obstruction, erosion, or detrusor failure.

Artificial Urinary Sphincter Infection

Infection remains a serious and devastating complication of any implant surgery. The rate of infection with initial AUS surgery is 1% to 3% (Gundian et al., 1989; Litwiller et al., 1996; Marks and Light, 1989; Montague and Angermeier, 2000) but may be as high as 10% in high-risk patients (see earlier). **Skin pathogens are the most commonly cultured organism, usually *Staphylococcus epidermidis* and *S. aureus*** (Licht et al., 1995). The introduction of the InhibiZone surface treatment combining rifampin and minocycline hydrochloride to the AUS cuff and pump was postulated to lead to a reduction in postoperative infection rates, although the reduced infection rate seen with penile implants (Carson, 2004) has not been replicated in the AUS literature (de Cógáin and Elliott, 2013). Late infections (>4 months) may represent indolent organisms introduced at the time of infection or by hematogenous spread. Therefore, **in men with AUS, antibiotics should be considered before urinary tract manipulation in accordance with AUA Best Practice Statements** (Wolf et al., 2008, updated 2012).

The initial presentation of an early postoperative AUS infection is usually scrotal pain, although erythema, edema, and frank purulence commonly accompany this symptom. **Because implant infections are generally not amenable to antibiotic therapy, in a patient presenting with infection or erosion of an artificial urinary sphincter or sling, explantation should be performed and reimplantation should be delayed** (Sandhu et al., 2019). Figs. 131.6 and 13 show the AUA/SUFU algorithm for AUS and male sling failure, respectively.



Male Sling Failure
Infection/erosion
Inadequate continence
Explant as much as possible and consider AUS 3 to 6 months later
• Place AUS (with or without sling explant)
OR
• Replace sling, only by providers who are trained in replacement procedures

AUS: Artificial Urinary Sphincter

FIG. 131.13 AUA/SUFU Algorithm for Sling Failure. (Reproduced from Sandhu et al., 2019, with permission.)

Immediate salvage of infected non-eroded AUS can be accomplished with complete device removal, antiseptic irrigation, and immediate reimplantation (Bell and Mulcahy, 2000; Bryan et al., 2002; Kowalczyk et al., 1996a,b). This procedure includes an irrigation regimen used in penile prosthesis salvage protocols (Mulcahy et al., 1995). Mulcahy and associates used this approach to salvage 7 of 8 patients with infected non-eroded AUS in a total of 9 operations (Bryan et al., 2002). In all cases the entire AUS was removed and the wounds were copiously irrigated according to a seven-solution protocol before a new system being implanted. Contraindications to prosthesis salvage include sepsis, ketoacidosis, necrotizing infection, device erosion, immunosuppression, and the finding of gross purulent material at the time of explantation.

Urethral Erosion

Urethral erosion is reported in 5% to 10% of AUS implantations and is as high as 35% in patients with multiple risk factors described earlier (Brant et al., 2014; Mock, 2015). Furlow introduced the concept of postoperative deactivation during the healing process to decrease pressure-induced ischemia and necrosis (Furlow and Barrett, 1985). **Delayed activation has lowered the risk of urethral erosion, especially in cases of reimplantation.** The secondary urethral erosion dropped from 18% to 1.3% with this technique (Motley and Barrett, 1990). Multiple well-established risk factors of erosion include prior radiation, hypertension, coronary artery disease, diabetes, and prior AUS revisions (Brant et al., 2014; Raj et al., 2006; Rivera et al., 2016). In addition, urethral catheterization (with or without cuff deactivation) is also a risk factor for urethral erosion (Seideman, 2013).

Although a recent study reported that only 25% of PRBs left in place at the time of AUS cuff explant because of erosion became infected (Rozanski et al., 2018), **we advocate for immediate removal of all the components in cases of erosion, because they are assumed to be infected** (Biardeau et al., 2016)**. Urethral injury has traditionally been managed with urethral catheter drainage and or suprapubic cystostomy** (Flynn and Webster, 2004; Kowalczyk et al., 1996a,b). Perineal wounds are considered infected and loosely approximated or allowed to close by secondary intention.

In an effort to decrease the risk of subsequent urethral stricture, several centers have evaluated the management of acute erosion with urethrorrhaphy or urethroplasty. The type of urethroplasty performed at the time of erosion has not been well studied and likely depends on the degree of urethral loss at the time of device explantation. Patients who underwent in situ urethral repair, with ventral approximation of the urethral mucosa without mobilization of the urethra, developed a urethral stricture in 38% of patients compared with 85% of patients who had urethral catheter drainage alone (Rozanski et al., 2014). In contrast, a multi-institutional study demonstrated a higher risk of stricture formation in patients with complete cuff erosion and did not demonstrate a statistically significant difference in stricture rate among patients who had their erosion managed with catheter (29%), urethrorrhaphy (repair of capsule) (40%), or anastamotic urethroplasty (14%) (Gross et al., 2017). This is a complex, heterogeneous group of patients with variable degrees of urethral loss resulting from cuff erosion. Further study is needed to identify which patients may be best suited for acute erosion urethroplasty or whether catheter placement alone is sufficient.

AUS reimplantation is considered only after urethral healing is confirmed by urethrography and a delay of 3 to 6 months is observed. Urethral patency must be confirmed after urethral erosion and cuff removal by cystoscopy or retrograde urethrogram before attempted device replacement (Frank et al., 2000; Kowalczyk et al., 1996a,b; Motley and Barrett, 1990). A new cuff should be placed either proximal or distal to the previous site. Significant scarring as well as a compromised vascular supply makes replacement of the cuff at the erosion site difficult and risky (Kowalczyk et al., 1996a,b; Motley and Barrett, 1990). The risk of repeat cuff erosion in patients undergoing AUS reimplantation has been shown to be as high as 35% in the first 6.7 months (Raj et al., 2006). Frank et al. (2000) **recommended nightly deactivation of the AUS in cases of reimplantation for prior erosion** and reported a successful outcome in 87% of de novo reimplantation after erosion or infection, with recurrent urethral erosion in 8.7%. **Use of the transcorporal approach in such cases may reduce the risk of urethral injury during the secondary surgery as well as potentially provide greater protection against subsequent erosion.**

Urethral Atrophy

Patients should be counseled that artificial urinary sphincters will likely lose effectiveness over time, and reoperations are common (Sandhu et al., 2019). **Urethral atrophy results from the chronic compression of the spongy tissue under the occlusive cuff. In contrast to device failure, the symptoms may be insidious in onset and progress slowly. This is considered one of the most common reasons for revision of the AUS. Treatment options include cuff downsizing, movement of the cuff to a more proximal or distal location, where the spongiosum may be thicker, transcorporal placement, or placement of a second cuff in tandem.** Simple replacement of the PRB with a higher-pressure reservoir to overcome urethral atrophy is no longer recommended because of risk of erosion (Raj et al., 2005).

Our approach is to downsize the cuff in the same location when possible. If the existing cuff is 4.0 cm, we reposition the cuff more proximally, when feasible, or more distally using the transcorporal technique if necessary, and measure the appropriate size cuff. Saffarian et al. (2003) reported a significant improvement in daily pad usage from 3.9 to 0.5 in 17 patients with urethral atrophy undergoing AUS. In a large series of secondary AUS surgery, the cuff was replaced in 142 cases of which 33% of cuffs were placed distal to the original location, 11% were placed proximal, and 52% were placed at the original cuff location (Raj et al., 2005). The cuffs were downsized in 56% of cases, unchanged in 30% and upsized in 13%, reflecting the new locations.

Recently the concept of subcuff atrophy has been questioned, and one high-volume center obtains acceptable results by assuming that all cases are mechanical failure and replaces the device with the same size cuff (Bugeja et al., 2016). In contrast, Srivastava et al. (2018) used retrograde urethral pressure profilometry to assess cuff coaptation and identified atrophy as the cause of AUS failure in 22% of cases.

Mechanical Failure

The historical incidence of mechanical failure has diminished substantially after introduction of the narrow-backed cuff (Elliott and Barrett, 1998). The change in design resulted in a decrease in nonmechanical failure from 17% to 9%, primarily because of a reduction in urethral atrophy. A decrease in mechanical failure from 21% to 7.6% was primarily the result of a reduction in cuff leak along with improvements in the synthetic material, which lessened the risk of fracture or kinking of the device. **Patients can generally expect a 7- to 10-year device life for the AUS. In the absence of infection or erosion, replacement of an isolated malfunctioning component may be feasible if the revision occurs within 3 years of implantation. These will most often be pump or cuff failures, which occur at a median of a year or less** (Srivastava et al., 2018)**. However, a slow leak from the PRB may be difficult to diagnose intraoperatively, and, if in doubt, total device replacement is prudent. Devices more than 3 years old most likely fail at the PRB; we generally replace the device in toto; however, approaches to selectively interrogate the PRB first, either with an ohmmeter** (Selph et al., 2015) **or a burette** (Srivastava et al., 2018)**, may allow the experienced implanter to avoid total replacement.**

Special Circumstances

The management of **urethral and vesicourethral anastomotic stricture** encountered *after* AUS implantation proposes a unique challenge. Stricture at the site of the AUS cuff may result from compression or ischemia and may indicate impending urethral erosion. One such bulbar urethral stricture was successfully managed with periodic dilation (Debell and Wessells, 2001). Others have successfully treated strictures proximal to an AUS with balloon dilation (Westney et al., 1992) or holmium laser through a flexible cystoscope or ureteroscope (Anger et al., 2005). In the event significant endoscopic manipulation is required proximal to the cuff site (e.g., transurethral resection of bladder tumor), our practice is to surgically uncouple the cuff for the duration of the endoscopic procedure.

The incidence of **urethral stricture after catheter management of erosion** is unknown, with no large series on AUS reporting this outcome. Patients who develop a significant urethral stricture after erosion may require urethroplasty before subsequent AUS placement. Patients with stress urinary incontinence following urethral reconstructive surgery may be offered artificial urinary sphincter and should be counseled that complications rates are higher (Sandhu et al., 2019). Patients undergoing AUS reimplantation 6 months after successful urethroplasty have an expected risk of erosion of 24% at 2 years' follow-up (Keihani et al., 2017). Transcorporal AUS placement in patients undergoing revision AUS may reduce the risk of subsequent erosion.

UI after cystectomy and neobladder reconstruction is a well-known entity. AUS placement in this group of patients is feasible, but not without a significant rate of complication. Patients with elevated postvoid residual were taught clean intermittent catheterization (CIC) after cuff deactivation. Incontinence improved in 76% of patients but with a 60% revision rate (O'Connor et al., 2002). This revision rate is likely due to the high bacterial colonization rate as well as risk associated with CIC. An important technical aspect in this group of patients is to avoid placing the PRB adjacent to the neobladder because of the risk of erosion into the neobladder or other adjacent bowel. We advocate making a counter-incision lateral away from the midline and placing the PRB posterior to the rectus muscle.

In patients with incontinence after prostate treatment and erectile dysfunction, a concomitant or staged procedure may be offered (Sandhu et al., 2019). **Dual implantation of AUS and inflatable penile prosthesis** is safe, feasible, and cost-effective for patients with UI and erectile dysfunction. Although the literature is limited, several small case series have shown that synchronous implantation of both devices can be performed, albeit with longer operative times (Kendirci et al., 2006; Rolle et al., 2012). Implantation can be performed through 1 penoscrotal incision or 2 incisions (penoscrotal, perineal).

Patients who have **an inflatable penile prosthesis requiring placement of a transcorporal AUS** represent a potentially complex scenario for the implant surgeon. Surgeons should attempt to avoid opening the capsule of the penile prosthesis to prevent potential contamination and direct contact of the two silicone devices. If this is unavoidable, separation of the two implants can be achieved by closing the tunical defect with tutoplast, donor pericardium, or other similar off-the-shelf material.

Sling Complications

The most commonly reported complications of male slings are perineal pain, urinary retention, infection, and rare cases of erosion. Retention is short lived and resolves within several weeks. Isolated cases have required release of the sling. **Large series with longer-term follow-up suggest rates of erosion and infection of 1% to 2%** (Cerruto et al., 2013; Zuckerman et al., 2014). Patients should be counseled as to the possibility of persistent pain and dysuria after slings, although such complications are extremely rare. Pain is typically related to the trocar introduction sites on the thigh and generally subsides; persistent severe pain may imply that the sling has been placed through the tendon of to adductor longus muscle and should be evaluated with appropriate imaging.

Key Points

- Device infection typically requires total explantation, but salvage procedures in select patients with device removal, antibiotic regimen washout, and reimplantation are feasible.
- Device erosion requires total explantation and catheter drainage.
- Troubleshooting of recurrent UI post-AUS requires a systematic and exhaustive evaluation.
- Cuff atrophy requires downsizing, repositioning, tandem cuff, or transcorporal surgery.

Long-Term Results of Artificial Urinary Sphincters and Slings

Outcomes of surgical correction of male UI depend on patient and device characteristics. First in importance is the severity of UI. Many urologic surgeons reserve sling surgery for mild to moderate degrees of incontinence, but severity is poorly characterized by pad number (see earlier). A difference in baseline incontinence between studies introduces unmeasured bias and makes comparisons of case series difficult. We have summarized available data in Table 131.1.

Montague and Angermeier (2000) reviewed the results of the AUS in 286 patients from 5 centers noting that on average 76% of patients were dry (dry 0–1 pads/day) and 13% were improved, for an overall success rate of 89% at a mean follow-up of 18 to 44 months. Revision of the device occurred because of erosion 5%, infection 3%, and mechanical failure 15%. Other studies have confirmed these results (Hajivassiliou, 1999; Venn et al., 2000). Although many patients still need minor protection with urinary pads, most are satisfied with the long-term outcome of the AUS (Dalkin et al., 2003; Haab et al., 1997; Montague and Angermeier, 2001; Wingate et al., 2017). Success rates for revision surgery compare favorably with initial surgery, although infection and erosion rates are higher (Raj et al., 2005). Differences among centers may be related to surgical volume, inclusion of secondary implants, as well as the sensitivity and accuracy of outcome measures. The long-term fate of patients implanted with transcorporal cuffs and the newly introduced 3.5-cm cuff remain to be determined (Hudak and Morey, 2011). The 3.5-cm cuff is an option for patients with urethral atrophy except in cases of prior radiation therapy or erosion (Brant et al., 2014; Lai and Boone, 2012; Simhan et al., 2015).

Initial success rates with transobturator slings are high, and outcomes appear to be durable beyond 3 years. One surgeon did not identify a learning curve in adoption of the transobturator male sling (Zuckerman et al., 2013), but other centers with less extensive experience with male urethral surgery, AUS, or female sling surgery may note greater variation in outcomes with initial cases.

The role of the transobturator AdVance sling in the armamentarium has been firmly established. Early promising results (Bauer et al., 2009) have been confirmed by other centers, and a persistent benefit with only modest deterioration over time (Li et al., 2012; Rehder et al., 2012; Zuckerman et al., 2014). Incontinence improvement at 3 years is reported between 73% and 77% in appropriately selected patients (Kowalik et al., 2015; Rehder et al., 2012; Zuckerman et al., 2014). Patient selection criteria are evolving, particularly with regard to cutoffs based on incontinence severity (e.g., pad number or weight). The poorer prognosis for patients having undergone prior adjuvant radiotherapy has been replicated in additional series (Torrey et al., 2013).

A recently performed meta-analysis supports multiple prior studies on the effectiveness of the AUS and Advance sling. This analysis did not compare effectiveness of the AUS to the sling, rather the published outcomes that are usually based on surgeon decision. Both devices reduced the pad number used per day by 3, with approximately 60% of men cured of UI and another 25% improved (Chen et al., 2017).

Success rates reported for the Virtue Quadratic Sling range from 32% to 100% based on UI severity, technique (fixation or no fixation), and primary outcome measure (Comiter et al., 2014; Ferro et al., 2017; McCall et al., 2016). In the longest running study (Ferro et al., 2017) all patients used a pad or less at 36 months, and improvements in most measures were significant. However, other studies used alternative definitions of success, such as no pad use, which makes comparison across studies difficult. In the only study without industry support, success was much lower (32%). Larger, rigorously designed studies, including principles enunciated by the FDA in its *Guidance for Industry and Food and Drug Administration Staff* (FDA, 2011), are necessary before more widespread dissemination of Virtue can be recommended.

The approach to failure of male sling is also evolving. Repeat male sling surgery was effective in several studies, with the caveat that selection criteria must be carefully considered (Martinez et al., 2015; Soljanik et al., 2010). Reoperation and implantation of AUS has been shown to have outcomes similar to those in surgically naive patients (Lentz et al., 2012), and in patients with persistent or recurrent stress urinary incontinence after sling, an artificial urinary sphincter is recommended (see Figure 131.13) (Sandhu et al., 2019).

The less-consistent outcomes seen with male perineal sling surgery may reflect variation in residual rhabdosphincter function or implantation techniques. In the future, quantitative assessment of rhabdosphincter function may be important in selection of patients for sling surgery or AUS. Finally, sling implantation inherently introduces greater variability in technique. Many factors are at play, including location of sling placement along the bulbar urethra, pelvic bony anatomy, degree of tension placed on the device, and other unmeasured influences. In contrast, the AUS occludes the bulbar urethra with a very high degree of reproducibility and mechanical reliability, allowing consistent results regardless of the degree of incontinence or experience of the surgeon.

Key Points

- AUS continues to provide a reliable solution to male UI of all degrees of severity across the range of first-time implantation to complex reoperative and high-risk patients.
- Transobturator slings such as AdVance and newer devices provide long-term durable outcomes for mild to moderate male UI after RP.

Future Directions

Improving the Quality of Evidence

It is estimated that more than 150,000 men have undergone AUS implant or sling device for the treatment of male stress incontinence (Van der Aa et al., 2013). Despite the large number of patients, the preponderance of clinical studies evaluating the long-term outcomes related to device implantation are small, retrospective single institution case series. This is highlighted by two recent reviews evaluating the quality of articles on surgical procedures for male stress UI. A Cochrane database review found only 1 randomized controlled trial evaluating surgery for male stress UI, whereas another review found that there have been no high-quality studies performed as defined by randomized controlled trial data or data registry data (IDEAL framework 3-4) (Barski et al., 2017; Silva et al., 2014). Consequently, there are many critical questions that remain unanswered or have been studied with insufficient power to properly direct patient and surgeon practice. Patient-reported outcome measures used to assess AUS outcomes have not been designed or validated for men with UI (Wingate et al., 2017). Other gaps include evaluation of the impact of radiotherapy on AUS and sling outcomes, how to best manage AUS erosions (i.e., in situ urethroplasty vs catheter), and how to manage urethral strictures after AUS erosion (Chertack et al., 2017; DeLay et al., 2018; Keihani et al., 2017; Rozanski et al., 2014; Srivastava et al., 2018).

Patients and urologic surgeons are likely to benefit from greater collaboration among institutions by participating in device registries and/or multi-institutional research studies, which offer the power to answer the field's most difficult questions regarding outcomes of male UI device surgery and the impact on patients' health-related quality of life. Patients are being accrued in the randomized controlled MASTER (male synthetic sling vs. AUS trial for men with urodynamic stress incontinence after prostate surgery) trial in the UK. The trial objective is to determine whether the Advance sling is non-inferior to the AUS for post-prostatectomy male UI based on clinical outcomes, complications, and cost-effectiveness (Constable et al., 2018). In addition, the European Urology Association Research Foundation in collaboration with Boston Scientific Corporation is enrolling a registry of patients in Europe with male UI undergoing AUS or sling placement. The primary outcome endpoint is cure rate, with secondary outcomes evaluating the time being incontinence free, time from revision, change in quality of life, and complications (US National Library of Medicine).

Training Paradigms

Implantation of AUS and sling can dramatically improve male UI, yet only 20% to 30% of urologists in the US continue to perform this surgery after training (Poon et al., 2012). Several hurdles limit the adoption of these procedures amongst practicing urologists: unclear indications for sling versus AUS; low case numbers in training; limited familiarity with perineal dissection; and lack of standardization of device implantation techniques. Strategies to increase dissemination are therefore needed during and after training. These may include innovations in preoperative assessment of sphincteric function to optimize assignment to sling surgery; development of simulation curricula or standardized cadaver-based training during graduate medical education; and invention of novel tools to improve intraoperative cuff sizing, sling tensioning, and other critical steps in device implantation.

Summary

The continued high rate of surgery for localized prostate cancer portends that male sphincteric UI will remain prevalent and require surgical treatment to improve symptoms and quality of life. The initial evaluation must include a focused history and physical examination, voiding diary, pad weight test, uroflowmetry and postvoid residual measurement, and in selected cases cystoscopy and pressure flow urodynamics. The AUS remains the gold standard treatment for moderate to severe male UI, especially in complex cases, with excellent overall success and acceptable complication rates. For mild to moderate UI in the absence of prior urethral surgery, radiation therapy, or detrusor acontractility, male slings provide efficacious alternatives. The outcomes after AUS and male sling cannot be fully compared because of differences in baseline incontinence severity, end points, follow-up, and patient numbers. Nevertheless, **regardless of severity, nearly 90% of men with sphincteric UI will have minimal leakage and acceptable quality of life related to urinary symptoms after surgical treatment with AUS.** Similar cured and improved rates for post-RP UI have been reported with transobturator slings. However, several caveats exist. It is likely that selection bias regarding UI severity and other factors exists in choosing a sling versus AUS at most institutions. Results of slings in radiated patients are inferior. The appropriateness of standard transobturator slings for incontinence of other causes (e.g., TURP, neurogenic, post-traumatic) requires further demonstration. No sling has been compared with AUS in a controlled clinical trial. Furthermore, perineal **sling implantation depends on subtle technical maneuvers relating to positioning and tensioning. Conversely, once the urethra has been circumferentially mobilized and measured, the effectiveness of AUS is largely independent of technique.** Thus the occasional implanter will be more likely to achieve success with AUS versus sling procedures, although the potential for erosion and mechanical failure will continue to drive the need for alternative solutions.

Bladder Surgery for Benign Disease

Paras H. Shah MD, Lee Richstone MD

Surgery of the urinary bladder and distal ureter often involves significant extirpative as well as reconstructive techniques, demanding skill and experience from the urologic surgeon. As a result of these technical challenges, bladder surgery is associated with significant potential for complication in inexperienced hands. In an attempt to minimize the morbidity of open surgery, minimally invasive techniques for surgery of the urinary bladder have been introduced and refined. Laparoscopic and robotic techniques can be used for essentially every bladder operation. In most cases, improved cosmetic results are accompanied by reductions in associated pain, duration of hospitalization, and recovery times. Nevertheless, open surgery remains a widely utilized strategy with proven long-standing efficacy with respect to outcomes.

Technology continues to drive the field forward, and natural orifice transluminal endoscopic surgery and laparoendoscopic single-site surgery (LESS) techniques have been employed to reduce further the incisions and morbidity associated with surgery of the urinary bladder. This chapter describes open, conventional laparoscopic, robotic, and LESS approaches to surgery of the distal ureter and the bladder, focusing on indications, techniques, complications, and outcomes (Box 132.1).

Bladder Anatomy and Surgical Considerations

The bladder is located in the anterior pelvis situated within the extraperitoneal compartment. The space of Retzius, also referred to as the *retropubic space*, separates the bladder from the pubic bone and transversalis fascia anteriorly and is composed of loose areolar tissue. Dissection of this space provides access to the anterior bladder wall.

The parietal peritoneum lining the anterior abdominal wall folds over the dome of the bladder, forming the peritoneal reflection and effectively separating the pelvic and abdominal cavities. Laterally, this peritoneal fold forms the peritoneal wings, which serve as the superior border of the lateral paravesical fossa and overlie the ductus deferens in males or form the broad ligament in females. These peritoneal attachments to the bladder can be divided to aid in bladder mobilization. Redundancy of the peritoneal reflection on the superior surface of the bladder can be appreciated posteriorly when the bladder is empty and is referred to as the *transverse vesical fold.*

The bladder is bordered on this lateral surface by the perivesical fat, which, when swept medially, exposes the lateral paravesical fossa in which reside the pelvic muscular sidewall, the obturator fossa, and the external and internal iliac vessels.

Within males, the most dependent portion of the peritoneal reflection occurs at the interface between the rectum and posterior bladder wall, referred to as the *rectovesical pouch.* The corresponding region in females is shallower and occurs between the anterior uterus and posterior bladder wall, referred to as the *vesicouterine pouch.* Incision of the peritoneal fold in these locations enables mobilization of the posterior bladder wall through caudal dissection within the fascial partition separating the bladder and prostate from the rectum in males or the bladder from the uterus and anterior vaginal wall in females.

The bladder derives the majority of its blood supply from the internal iliac artery, which provides blood flow through a rich vascular network emanating from the superior and inferior vesical arteries. The superior vesical artery originates off the umbilical artery, which itself is a branch of the internal iliac artery. Ligation of the contralateral superior vesical artery often allows for cephalad mobilization of the bladder. The inferior vesical artery branches directly off the anterior division of the internal iliac artery, although in females, it is considered a branch of the vaginal artery emanating off of the internal iliac artery. The ureter enters the bladder parallel to this pedicle.

The ureters course over the bifurcation of the common iliac arteries after which they deviate medially within the pelvic cavity to insert into the posterolateral aspect of the base of the bladder. Several aspects to the ureteral anatomy within the pelvis deserve mention. The umbilical artery may be ligated in some cases to support caudal ureteral dissection. In males, the ureter courses under the vas deferens in close proximity to the tip of the seminal vesicles before entering the bladder. In females, the ureters course below the uterine vessels, which originate off the anterior division of the internal iliac and travel through the broad ligament as part of the cardinal ligament.

Bladder Diverticulectomy

Description

Bladder diverticula are outpouchings of the bladder wall devoid of a functional muscularis propria lining (Kelalis and McLean, 1967). The primary layers constituting the wall of diverticula are the mucosa and underlying lamina propria tissue. Beyond this, scattered detrusor muscle fibers may be observed in an architecturally disorganized fashion, precluding coordinated contraction of the diverticulum (Kelalis and McLean, 1967). As such, urinary stasis and associated sequela may prompt clinical symptoms and the need for intervention (Fox et al., 1962). Overlying the exterior of diverticula is the adventitial layer of the bladder wall around which a fibrous capsule may form. This capsule serves an important role during surgical dissection if resection of the diverticulum is undertaken (Kelalis and McLean, 1967).

Among adults, acquired bladder diverticula are most frequently encountered in the setting of bladder outlet obstruction as a result of high voiding pressures. A male predominance is reported as benign prostate hyperplasia is responsible for the majority of acquired diverticula, although urethral stricture disease and pelvic organ prolapse may also cause outlet obstruction in women (Kelalis and McLean, 1967). Individuals with neurogenic bladder who have poor wall compliance may also have high intravesical pressures contributing to the formation of bladder diverticula. Diverticula acquired in the context of outlet obstruction or poor bladder compliance can be multiple in nature and vary in size, factors that strongly influence the ultimate need for intervention and treatment selection.

Most acquired diverticula are asymptomatic and thus discovered incidentally on imaging or cystoscopic examination for alternative reasons, including for conditions that underlie their formation. Symptoms related to the presence of diverticula are primarily caused by the associated urinary stasis and include urinary tract infection and formation of bladder calculi (Melekos et al., 1987) (Fig. 132.1). As diverticula may hold larges volume of urine, they may also contribute to the sensation of incomplete bladder emptying. Less often, large-caliber diverticula may extrinsically compress the ureter near its insertion into the bladder, resulting in ureteral obstruction and hydronephrosis (Livne and Gonzales, 1985). Several studies have also observed increased risk for bladder cancer within diverticula (Faysal and Freiha, 1981); a thorough evaluation is thus necessary before any intervention.

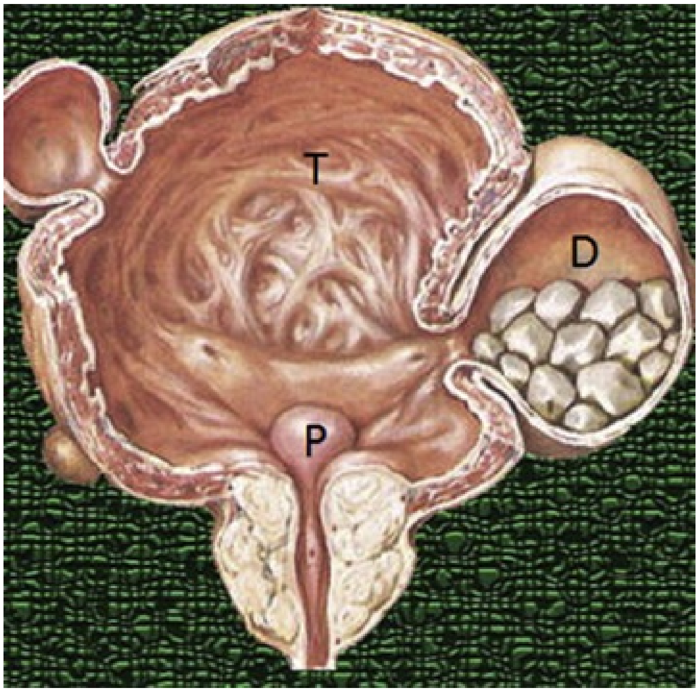

FIG. 132.1 Large left bladder diverticulum *(D)* seen with calculus secondary to stasis. Trabeculations in bladder wall *(T)* indicate diverticula formation in setting of bladder outlet obstruction caused by benign prostate hyperplasia *(P).*

A congenital bladder diverticulum is more commonly encountered in the pediatric population. Contrary to acquired diverticula in adults, the underlying mechanism involves an intrinsic weakness in the bladder musculature rather than outlet obstruction or neurogenic pathology (Blane et al., 1994). Nevertheless, a substantial proportion of individuals with congenital diverticula have voiding dysfunction syndromes, necessitating an evaluation for bladder outlet obstruction and neurogenic dysfunction in these populations as well.

Congenital diverticula are often solitary in nature and situated posterolaterally within the bladder in close proximity to the ureterovesical interface, in which case they are referred to as *Hutch diverticula* (Pieretti et al., 1999). As a consequence of the detrusor dysfunction associated with herniation of the bladder wall in this location, vesicoureteral reflux (VUR) is generally present and may contribute to clinical manifestations such as hydronephrosis or pyelonephritis. This is an important consideration when managing such diverticula as surgical planning should involve ureteral reimplantation.

Less common scenarios associated with the formation of bladder diverticula in adults include pediatric neurogenic and bladder outlet obstruction conditions (e.g., posterior urethral valves or prune belly syndrome), genetic connective tissue disorders (e.g., Ehlers-Danlos or Williams syndrome), and iatrogenic disruption of the bladder, most often in women who have undergone anti-incontinence procedures.

Evaluation and Surgical Indications

The evaluation of bladder diverticula is multifaceted, particularly when intervention is planned. Cystoscopy is a central component to the workup as it enables direct anatomic inspection of the diverticulum and permits evaluation for the presence of bladder malignancy, which may alter the treatment landscape. Important features to note during cystoscopy include the nearness of the diverticulum mouth to the ureteral orifices, the number of diverticula present, the size of the diverticulum mouth, and an approximate volume calibration. All diverticula should be entered if possible and every effort made to inspect the wall as an increased risk for bladder cancer has been reported. Additionally, urinary stasis within the diverticulum may contribute to the formation of bladder stones, which can be managed simultaneously with diverticulectomy. Trabeculations along the bladder wall may offer insight into the disease process contributing to the formation of diverticula as their presence may indicate bladder outlet obstruction. At the time of cystoscopy, the presence of prostatic lobar hypertrophy (particularly an intravesical component) and urethral stricture or bladder neck contracture should be noted as these would likely require management before or at the time of diverticulum treatment.

Voiding cystourethrogram (VCUG) may be performed as it offers a wealth of information regarding the structural properties of diverticula (e.g., location, number) and the anatomic aspects of any underlying conditions (Fig. 132.2). A reliable estimate of diverticulum size is offered by VCUG, which will influence treatment selection. In addition, diverticula that may have been missed on cystoscopic examination, particularly in the setting of heavy bladder trabeculation, may be elucidated. The concomitant presence of reflux and the proximity of the diverticulum to the ureter can be reliably evaluated on VCUG as well; this offers insight into whether preoperative stent placement is necessary to aid in identification and/or protection of the ureter or if a simultaneous ureteral reimplantation is necessary. Information on the presence of bladder neck obstruction, such as that caused by bladder neck hypertrophy, function bladder neck obstruction, detrusor-bladder neck dyssynergia, posterior urethral valves, or urethral stricture disease, can also be garnered from this study.

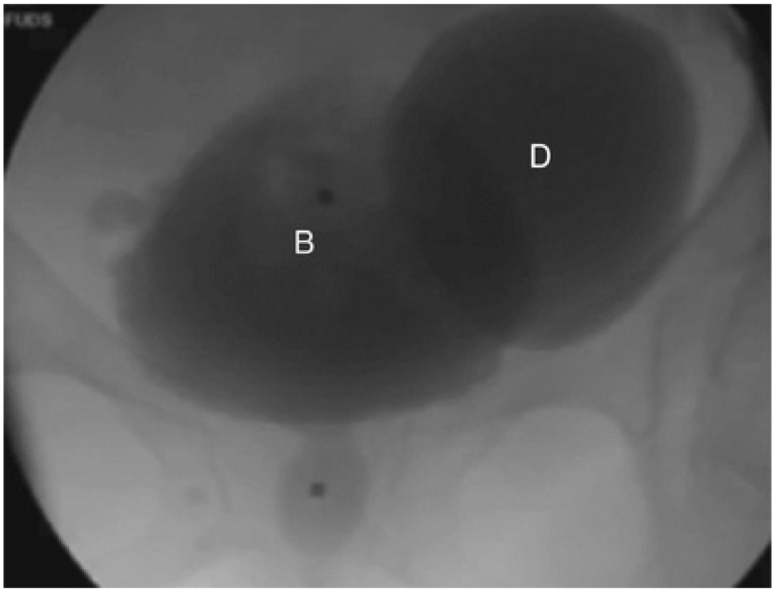

FIG. 132.2 Voiding cystourethrogram delineating bladder diverticulum *(D)* and bladder *(B).* (Modified from Chandhoke RA, Ghoniem GM. Transurethral electrovaporization of bladder diverticulum: an alternative to open or laparoscopic bladder diverticulectomy. *J Endourol Case Rep* 1[1]:11–13, 2015.)

The final study necessary before treatment planning involves imaging of the upper tracts. Ideally, triphasic computed tomography (CT) of the abdomen and pelvis, placing emphasis on excretory-phase imaging, helps characterize the concomitant presence of hydronephrosis, which may result from VUR or extrinsic ureteral compression by the diverticulum (Fig. 132.3). The proximity of the ureter to the diverticulum is also nicely delineated in this study (Fig. 132.4). CT imaging of the pelvis represents an invaluable tool in the workup as it enables evaluation of the number, size, and location of diverticula. In the event a contrast study cannot be performed, ultrasonography or noncontrast CT imaging of the kidneys should be done to evaluate for hydronephrosis combined with intraoperative retrograde pyelogram and cystogram to more comprehensively characterize the anatomic proximity of the diverticulum and ureter and evaluate for ureteral obstruction. Magnetic resonance urography may also be considered.

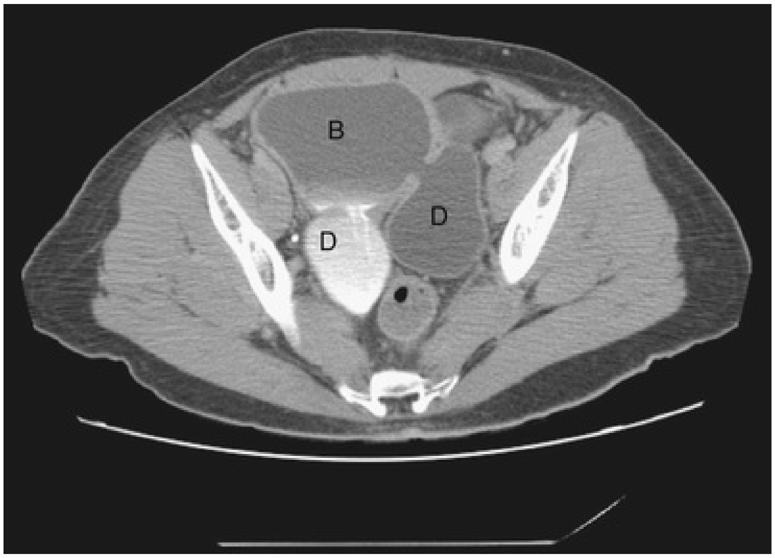

FIG. 132.3 Computed tomography urogram of the abdomen/pelvis demonstrating four bladder diverticula. Contiguity between true bladder *(B)* and two posterior bladder diverticula *(D)* is demonstrated.

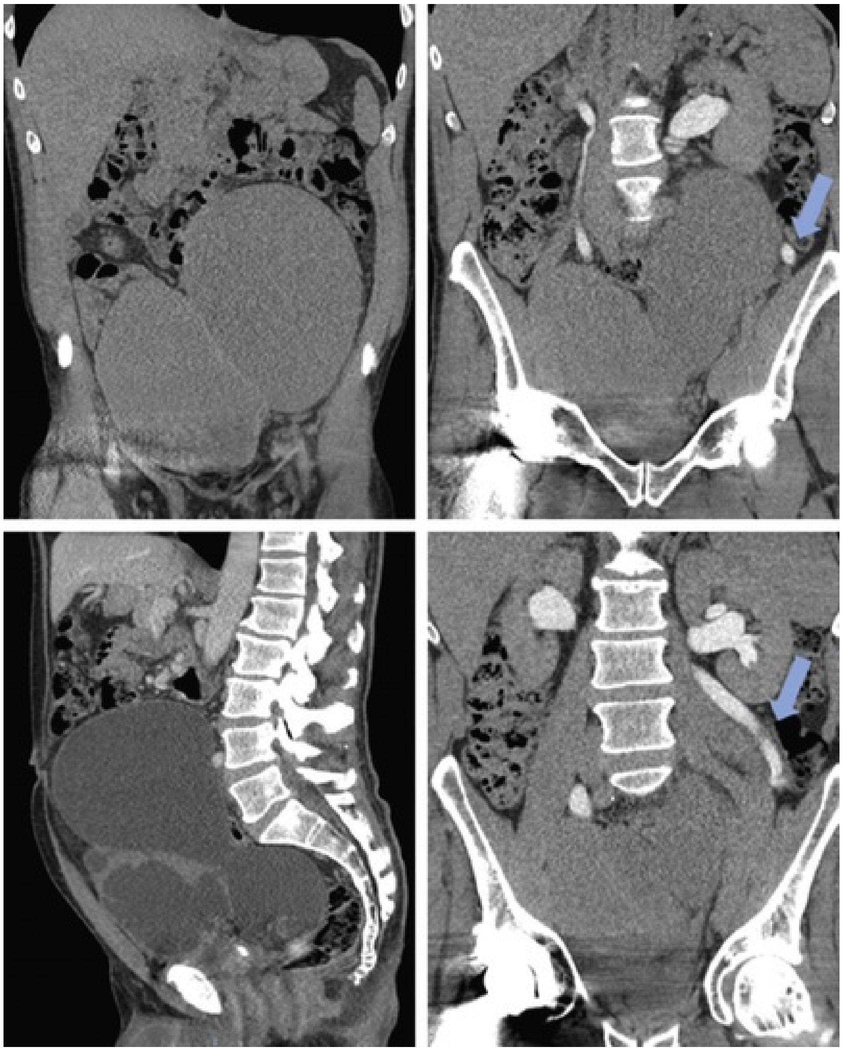

FIG. 132.4 Computed tomography of the abdomen/pelvis demonstrating large bladder diverticula in coronal *(top, left)* and sagittal *(bottom, left)* planes. Lateral displacement of the ureter *(arrow)* caused by the diverticulum can be appreciated on excretory phase imaging *(right).* (Courtesy of Lee Richstone, MD.)

As the majority of acquired bladder diverticula form in the setting of bladder outlet obstruction, and less often neurogenic dysfunction, ancillary studies should be performed to better characterize these conditions, as treatment for these disease states is necessary before or at the same time the bladder diverticulum is managed. In this regard, patients may undergo measurement of their urinary flow rate or undergo formal urodynamics testing to characterize detrusor contractile capacity and voiding pressures. Transrectal ultrasonography may be used to estimate prostate volume in patients undergoing procedural evaluation for benign prostatic hyperplasia (BPH), although CT imaging and cystoscopy, performed as part of the workup for a diverticulum, may also offer information regarding prostate size and extent of obstruction.

A urine cytology should be done in all patients given the association with bladder cancer. A negative urine culture should be confirmed before any surgical intervention.

Small, asymptomatic bladder diverticula without associated complications can be observed or treated with cystoscopic fulgaration (Clayman et al., 1984; Orandi, 1977; Vitale and Woodside, 1979) or resection. Diverticulectomy is indicated for large diverticula with incomplete emptying, chronic or repeated urinary tract infection, bladder calculi, or pain. Bladder diverticulum that result in ureteral reflux or obstruction also require diverticulectomy, often combined with ureteral reimplantation. The presence of bladder malignancy within a diverticulum is an indication for partial or radical cystectomy (Golijanin et al., 2003).

Surgical Technique

Since Czerny's first description of diverticulectomy in 1897 (Knappenberger et al., 1960), the surgical treatment of bladder diverticula has evolved from open surgery, to endoscopic procedures, to laparoscopic and robotic techniques.

Transperitoneal laparoscopic bladder diverticulectomy (LBD) was first introduced in 1992 (Das, 1992; Parra et al., 1992), and, since then, numerous subsequent reports have demonstrated the reproducibility of this technique via transvesical and extravesical approaches (Flasko et al., 2007; Nadler et al., 1995; Shah et al., 2006). Robotic bladder diverticulectomy (RBD) was subsequently described in 2007 (Macejko et al., 2008; Meeks et al., 2009; Myer and Wagner, 2007; Rao et al., 2007; Tareen et al., 2008) and mimics the laparoscopic technique, aids the surgeon without extensive laparoscopic experience, and provides a comfortable ergonomic platform for working in the deep pelvis.

When an open approach is utilized, it is possible to remain extraperitoneal, including for posteriorly situated diverticula, whereas during laparoscopic and robotic surgery, a transperitoneal approach may be preferable given this provides a wide and generous working space, and fewer reports exist detailing outcomes associated with an extravesical approach (Flasko et al., 2007; Nadler et al., 1995; Shah et al., 2006). Extraperitoneal surgery has the advantage of reducing risk for visceral injury and intraperitoneal urine leak, which can be a major source of morbidity.

The choice of surgical technique for bladder diverticulectomy depends on numerous factors, including the number and location of diverticula, proximity of the diverticulum to the ureter, and the need for concomitant ureteral or bladder outlet surgery. Complex (large, posteriorly situated) and multiple diverticula requiring concomitant ureteral reimplantation traditionally are managed with an open approach, although a laparoscopic or robotic approach may be pursued, provided the surgeon has sufficient experience and skill.

Various alternative approaches to laparoscopic diverticulectomy have been described in attempts to minimize morbidity further. Transvesical pneumovesicoscopic diverticulectomy has been described involving the cystoscopic establishment of carbon dioxide pneumovesicum, with subsequent transabdominal trocar placement directly into the bladder (Badawy et al., 2008; Marte et al., 2010). LESS surgery has been employed to address bladder diverticula as well via a transabdominal (Stolzenburg et al., 2011) and transvesical approach (Roslan et al., 2012a).

The underlying cause of diverticula formation should be addressed before or at the time of diverticulectomy, including relief of bladder outlet obstruction or augmentation cystoplasty in cases of neurogenic bladder. When bladder outlet obstruction is caused by BPH, surgery can be performed concomitantly, either immediately before or after resection of the diverticulum. Options for management include transurethral endoscopic procedures or extirpative interventions such as suprapubic prostatectomy, particularly for a higher burden of disease. Laparoscopic or robotic simple prostatectomy also can be performed at the time of LBD or RBD (Magera et al., 2008). If endoscopic management is pursued for bladder outlet obstruction, it should be performed before diverticulectomy to avoid risking perforation of the bladder from tension being placed on the suture lines by irrigation fluid.

Open Technique

Intravesical Approach.

The patient is placed on the operating table in a supine position with the anterior superior iliac spine positioned over the break of the table. The table is placed into slight flexion to facilitate entry into the retropubic space of Retzius (Fig. 132.5A). The genitalia and intraumbilical aspect of the abdomen is prepped and draped in the standard sterile fashion. An 18-Fr Foley catheter is placed into the bladder on the sterile field. The bladder is distended with approximately 200 mL of sterile water, and the catheter is plugged to retain irrigant fluid within the bladder. Alternatively, flexible cystoscopy can be performed at the beginning of the case, and a guidewire can be used to catheterize the diverticulum with a Councill-tip catheter; instillation of fluid would permit distension of the diverticulum and aid in intraoperative localization (Fig. 132.6). In cases in which the bladder diverticulum is in close proximity to the ureter, a ureteral catheter may be placed.

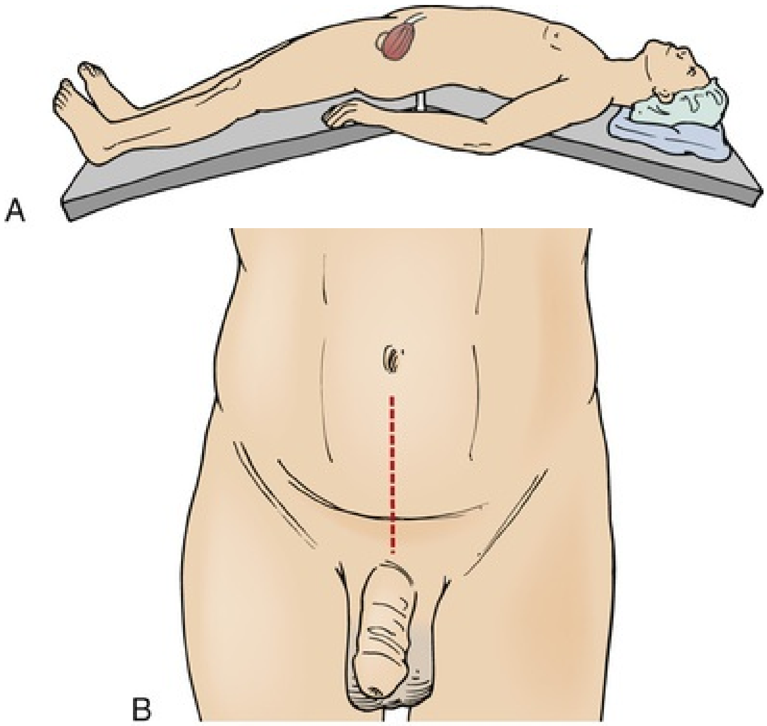

FIG. 132.5 Patient positioning and incision for open diverticulectomy. (A) Patient placed supine with operating table flexed. (B) Lower midline incision.

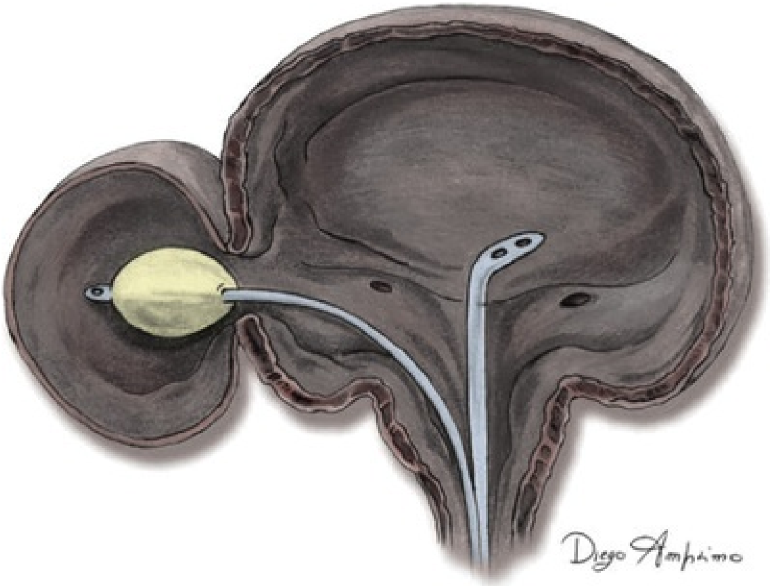

FIG. 132.6 Selective catheterization of the bladder diverticulum with a Councill catheter. A Foley catheter in the bladder permits selective distention of the diverticulum to aid in diverticular identification and dissection. Ureteral catheterization aids in ureteral identification to avoid injury. (Modified from Porpiglia F, Tarabuzzi R, Cossu M, et al. Sequential transurethral resection of the prostate and laparoscopic bladder diverticulectomy: comparison with open surgery. *Urology* 60[6]:1045–1049, 2002.)

A midline infraumbilical incision is made down to the level of the pubic symphysis (see Fig. 132.5B). The subcutaneous tissue is divided with electrocautery down to the rectus fascia. The rectus fascia is divided the length of the incision along the linea alba, exposing the underlying rectus abdominus muscle. The bellies of the rectus abdominus muscle are split the length of the incision after which the transversalis fascia is incised to reveal the preperitoneal fat above and the space of Retzius below. Distension of the bladder will have displaced the peritoneal reflection cephalad, enabling easier entry into the space of Retzius. The bladder may be distended further at this time to facilitate cephalad displacement of the peritoneum. Using a sponge-stick, the space of Retzius is developed bluntly as are the lateral pelvic gutters on either side of the bladder by pushing the perivesical fat medially. During this maneuver, the peritoneal reflection can be swept upward further off the bladder dome to minimize risk for inadvertent entry into the peritoneal cavity. At this time, a self-retaining retractor is placed to aid in exposure.

With the bladder distended, electrocautery is used to make a vertical cystotomy down the midline from the anterior dome of bladder to just proximal to the bladder neck. The irrigant fluid within the bladder should be aspirated with a suction device as the cystotomy is lengthened. A 2-0 polyglactin suture is placed transmurally at the apices of the bladder incision to minimize risk for tearing the bladder wall. At this time, all irrigant fluid should be aspirated from the bladder and the bladder mucosa carefully inspected to ensure that there are no suspicious lesions. Deeper blades can be placed on the self-retaining retractor to gently retract the bladder walls and facilitate exposure; alternatively, this can be done with a handheld deep blade retractor.

The ureteral orifices should be identified and their proximity to the bladder diverticulum noted. If there is concern regarding nearness of the ureter to the diverticulum, a 5-Fr ureteral catheter can be inserted into the ureter. Once the mouth of the diverticulum is identified, an attempt can be made to evert the diverticulum into the bladder lumen by passing an Allis clamp through the neck of the diverticulum and grasping its base. Once the diverticulum is everted, the mucosa is incised circumferentially around the neck of the diverticulum with an approximate 0.5-cm margin and continued down through to the submucosal connective tissue, freeing the diverticulum off the bladder wall.

If eversion of the diverticulum is not possible, a circumferential incision of the mucosa approximately 0.5 cm from the mouth of the diverticulum is made and carried down into the submucosal connective tissue (Fig. 132.7A). As diverticula often have a fibrous pseudocapsule that has formed around the adventitial layer, a combination of blunt and sharp dissection is used to exploit this plane and dissect the diverticulum free from its overlying capsule (see Fig. 132.7B). An Allis clamp placed on the neck of the diverticulum after incision of the mucosa can be used to generate countertraction as this cleavage plane is created between the diverticular sac and the fibrous capsule; The Allis clamp can be repositioned as needed around the perimeter of the diverticular neck to provide appropriate countertraction as the diverticulum is mobilized in a circumferential manner. Eventually, the diverticulum will be freed from its overlying capsule and removed in its entirety (see Fig. 132.7C).

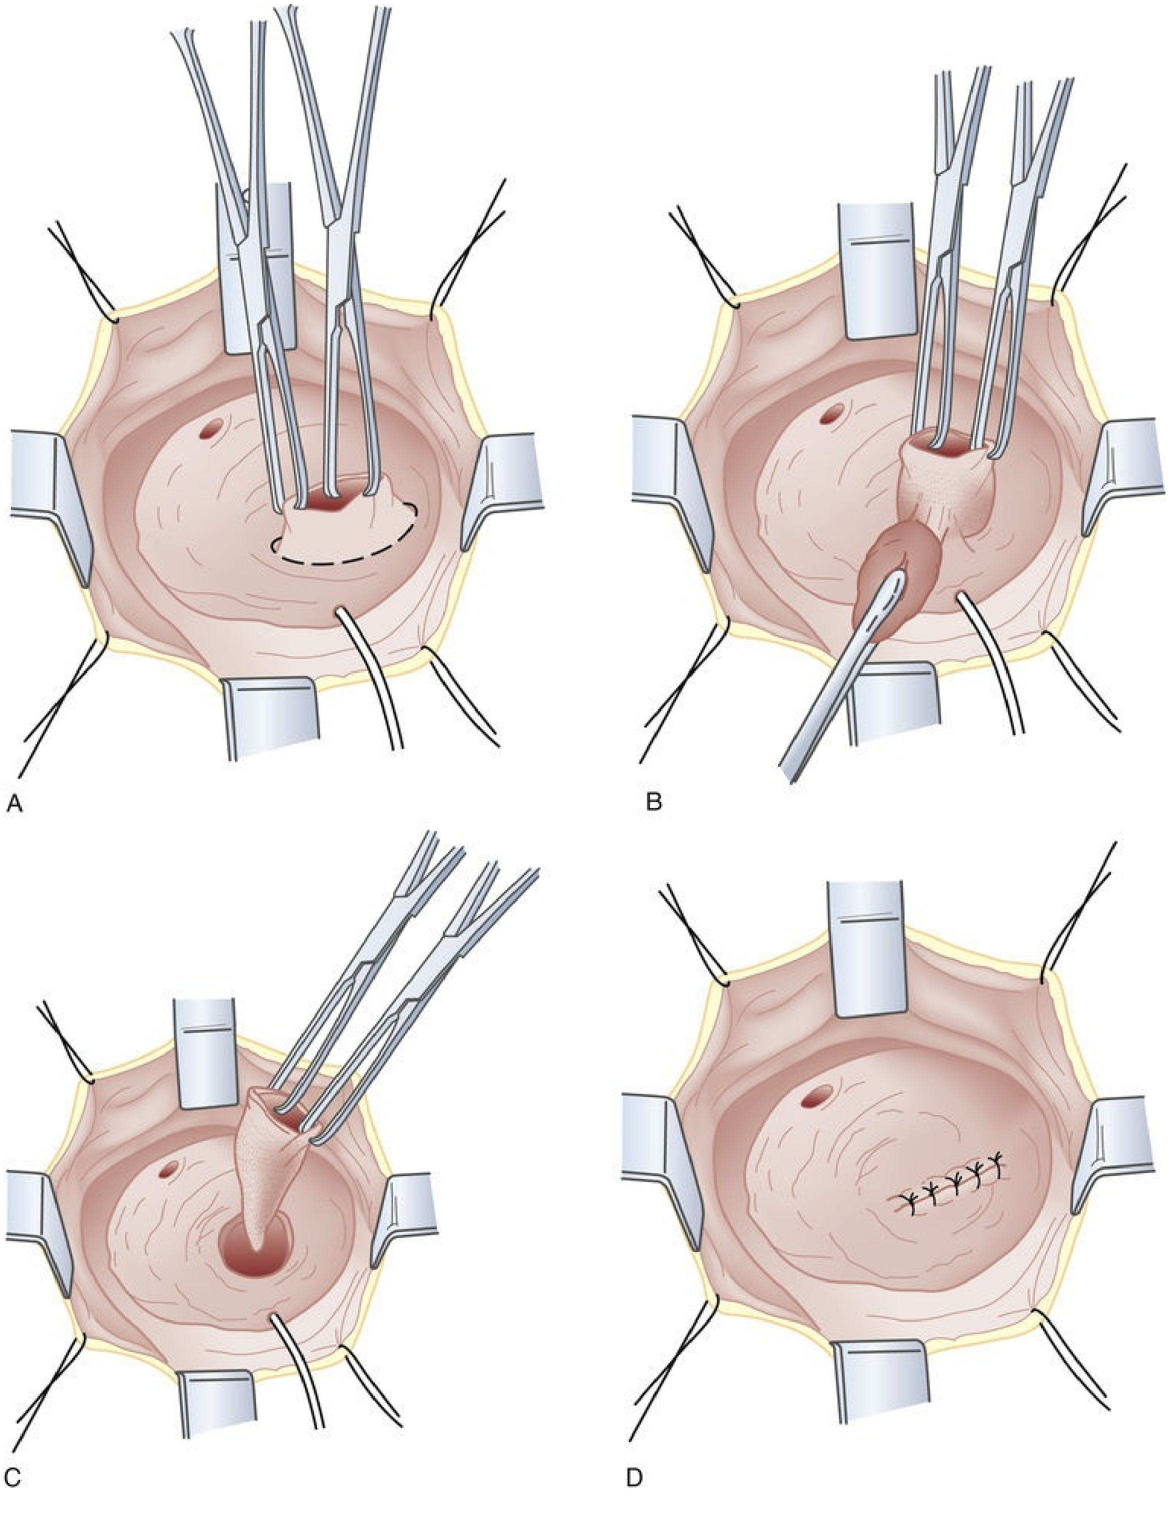

FIG. 132.7 Intravesical technique for bladder diverticulectomy. (A) The neck of the bladder diverticulum is identified intravesically. With the aid of Allis clamps, a circumferential incision is made through the mucosa into underlying connective tissue later. (B) The cleavage plane between the adventitial wall of the diverticulum and the overlying capsule is developed

with sharp and blunt dissection. (C) The diverticulum is freed from its overlying capsule and delivered into the bladder. (D) The bladder wall defect closed. No drain has to be left in remnant capsule.

The bladder wall defect at the site of diverticular resection should be closed in a two-layer running fashion using 2-0 polyglactin suture, with care taken to ensure a secure seromuscular closure to minimize the risk for recurrence (see Fig. 132.7D). The initial urinary catheter is exchanged for a larger-bore Foley catheter (e.g., 22-Fr). With the catheter in position, the cystotomy is closed in a two-layer running fashion with 2-0 polyglactin suture; the closure should allow for apposition of the mucosal layer first followed by the seromuscular layer. The integrity of the cystotomy closure and the bladder wall defect at the site of diverticulum removal should be tested by gently filling the bladder with 300 mL of sterile water. Any areas of fluid extravasation should be reinforced with figure-of-eight 2-0 polyglactin suture.

Placement of a suprapubic catheter is generally not necessary but may be placed at the surgeon's discretion to maximize drainage and minimize tension on the suture lines at the site of bladder closure. A separate punch cystotomy should be made lateral to the midline cystotomy before closure. The suprapubic catheter should be threaded into the bladder under direct visualization and secured to the bladder wall using 2-0 polyglactin suture in a purse-string fashion. Under direct visualization, a separate stab incision is made through the skin and underlying fascia lateral to the rectus belly with the aid of a tonsil clamp. The suprapubic catheter is brought out to the skin and secured with nonabsorbable suture.

A pelvic drain should be placed, ideally, anterior to the cystotomy curving into the lateral pelvic gutter lateralized to the site of diverticulectomy. This is brought out through the skin through a separate stab incision and secured using nonabsorbable suture. The drain should be placed to self-suction.

The fascia may be closed in either a continuous or interrupted fashion. The subcutaneous wound is irrigated, after which the skin is closed.

Combined Intra-Extravesical Approach.

The combined intra-extravesical approach to excision of a bladder diverticulum begins with many of the same initial steps involved in the intravesical technique. Once the cystotomy is made and the mouth of the bladder diverticulum identified, a circumferential incision of the mucosa approximately 0.5 cm from the mouth of the diverticulum is made and carried down into the submucosal connective tissue.

Subsequently, a finger or blunt curved instrument (e.g., metal suction tip) can be placed into the diverticular sac to allow anterior traction to be applied on the diverticular sac in a manner that brings the extravesical portion into surgical view (Fig. 132.8A). A Kittner dissection sponge can be used to gently tease the perivesical fat off the external surface of the diverticular sac and free it from surrounding tissue. This enables better visualization of the interface between the external surface of the diverticulum and the extravesical bladder surface.

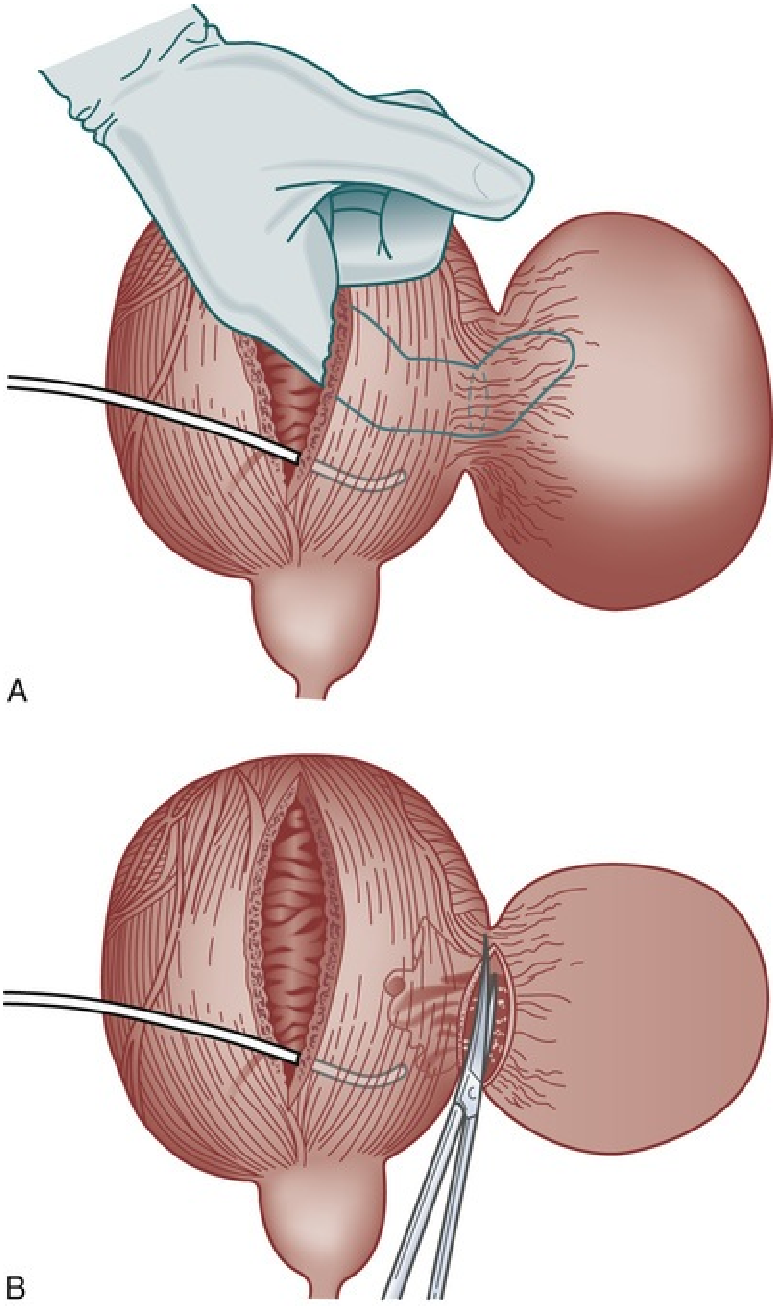

FIG. 132.8 Combined intra-extravesical technique for bladder diverticulectomy. (A) After gaining access to the bladder, the bladder neck is identified and circumferential incision is made through the mucosa into the underlying connective tissue. (B) A finger is placed into the diverticulum sac to allow for anterior displacement into the surgical field, and an incision is made circumferentially around the neck of the diverticulum along its extravesical surface. The diverticulum and overlying capsule are dissected free from surrounding tissue and removed. Alternatively, the detached diverticulum is dissected off its overlying capsule and removed.

With the neck of the diverticulum having been circumscribed intravesically with electrocautery, placement of anterior-outward traction on the diverticular sac should more readily expose the extravesical surface of the diverticular neck. The extravesical surface of the diverticular neck is circumferentially incised with electrocautery, freeing the diverticulum off the bladder wall (see Fig. 132.8B). It is important to bear in mind that as the diverticular neck is incised circumferentially on its extravesical surface, continuity should be established with the intravesically incised mucosal rim around the diverticular neck. Failure to do this may create a new dissection plane during extravesical dissection that leads to resection of excess bladder wall tissue.

Once the diverticulum neck is freed from the bladder wall, it remains within the surrounding pseudocapsule, which itself can be adherent to the surrounding perivesical tissue. The diverticular sac is dissected free from the pseudocapsule using a combination of blunt (i.e., a Kittner dissection sponge) and sharp dissection. Placement of Allis clamps at the neck of the disconnected diverticulum will offer countertraction to aid in dissection of the diverticulum off the overlying capsule.

The bladder wall defect can be closed using either the intravesical or extravesical route in a two-layer running fashion using 2-0 polyglactin suture.

Laparoscopic and Robotic Techniques

The patient is placed in a dorsal lithotomy position with the arms secured to the side and hips abducted (Fig. 132.9). The abdomen up to the level of umbilical and the groin are prepped and draped.

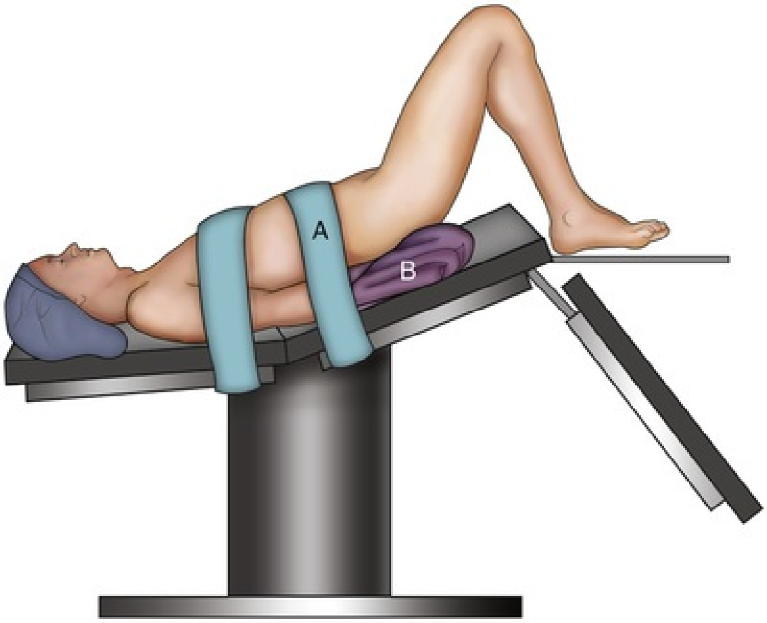

FIG. 132.9 Positioning for robotic and laparoscopic diverticulectomy. The patient is positioned in the dorsal lithotomy position using standard operative stirrups and then placed into the Trendelenburg position. All pressure points are protected using standard egg crate foam padding. (A) Cross-shoulder harness made by four strips of egg-crate foam padding. Each strip is 6 × 24 inches, and two strips are used on each side of the patient creating an "X" configuration across the patient's chest. The pads are secured to the operating table using cloth tape.

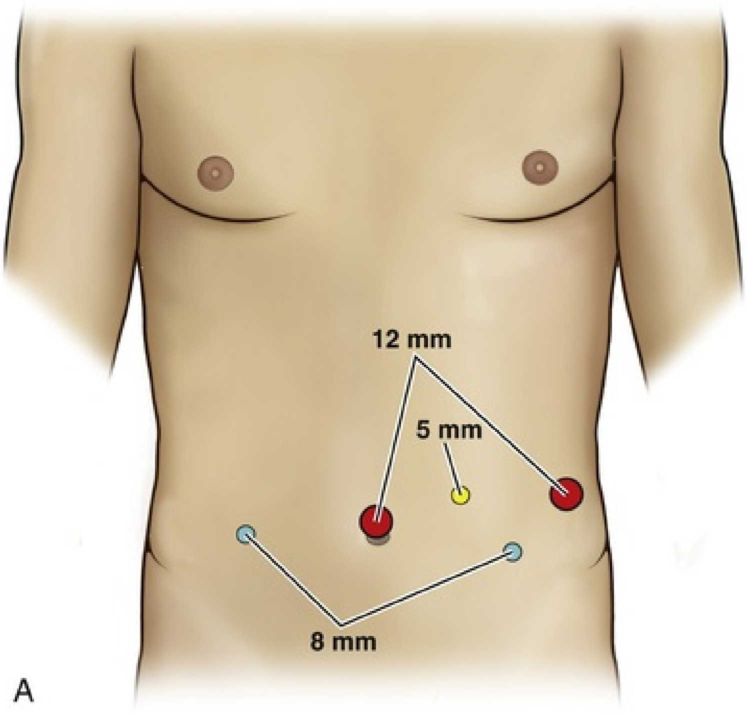
Before port placement, flexible cystoscopy can be performed for ureteral catheterization if necessary. Selective catheterization of the diverticulum can also be performed by placing a Councill-tip catheter over a guidewire into the diverticulum and a separate Foley catheter into the bladder proper for selective filling and intraoperative identification of bladder diverticula (Khonsari et al., 2004; Nadler et al., 1995; Porpiglia et al., 2002), as depicted in Fig. 132.6.

Alternatively, real-time illumination of the diverticulum with a flexible cystoscope is a useful aid in identifying the diverticulum, as described later (Jarrett et al., 1995; Nadler et al., 1995; Parra et al., 1992). In our experience, this is particularly valuable in patients with multiple diverticula in whom separate catheterization of each diverticulum is not practical. Intravesical methylene blue also has been described as an aid to identify the bladder neck during robotic diverticulectomy (Moore et al., 2012).

For both LBD and RBD being performed by a transperitoneal approach, a Veress needle is placed through the umbilicus into the peritoneal cavity, and pneumoperitoneum of 15 mm Hg is established. Alternatively, a subcostal location may be used for placement of the Veress needle in patients with prior history of abdominal surgery (Gaunay et al., 2016). The table is subsequently placed into the steep Trendelenburg position, which aids in visualization of the pelvic cavity by displacing the intestinal contents cephalad (see Fig. 132.9).

Trocars for LBD and RBD are positioned as depicted in Fig. 132.10. In the case of robotic surgery, the ports are placed beginning with the camera port in the midline approximately 2 cm above the umbilicus (see Fig. 132.10A); the incision for camera port placement should reflect the model of the DaVinci (Intuitive Surgical, Sunnyvale, CA) surgical system being used, as the Si unit utilizes a 12-mm port and the Xi unit uses an 8-mm port. The endoscope is inserted, and the abdominal cavity is inspected to ensure that there is no injury. The remaining 8-mm robotic ports should be placed under direct visualization.



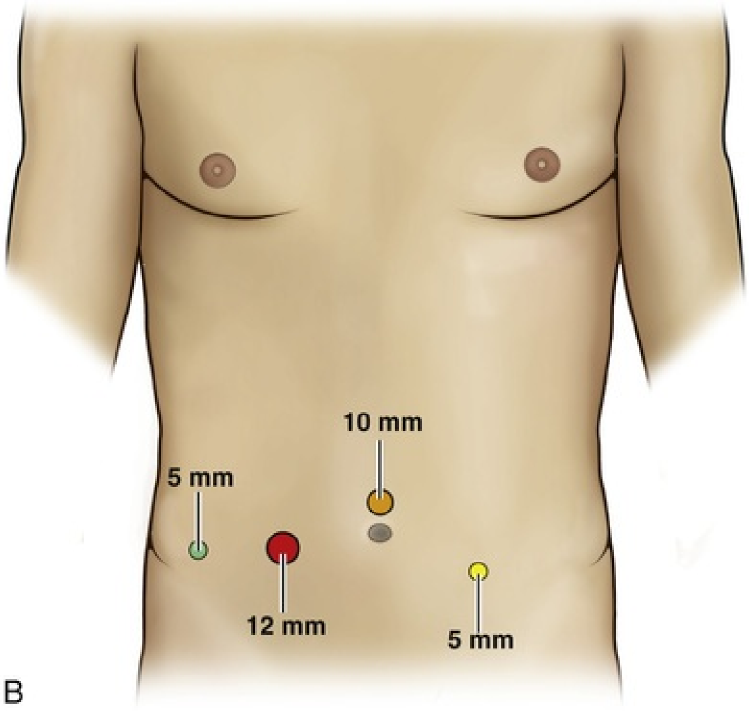


FIG. 132.10 Port placement. (A) Robotic bladder diverticulectomy. A 12-mm port at the umbilicus is employed for the endoscope. Two 8-mm robotic trocars are placed 10 cm inferolaterally at the pararectus location. At the surgeon's discretion, assistant ports are placed as needed; options include a 5-mm trocar (placed halfway between the camera and robotic trocar) and/or a 12-mm trocar (two fingerbreadths above the anterior superior iliac spine). If needed, an additional 8-mm trocar can be used for the fourth arm of the robot two fingerbreadths above the contralateral anterior superior iliac spine. (B) Laparoscopic bladder diverticulectomy. A 10-mm port at the umbilicus is employed for the endoscope. For a right-handed surgeon, working ports include a 12-mm and a 5-mm trocar at the right and left pararectus location, respectively. An optional 5-mm trocar can be placed approximately 2 cm cephalad and medial to the anterior superior iliac spine (depicted in *green*).

Two 8-mm robotic ports are placed on either side of midline caudal to the camera port and at the level of the umbilicus. These should be placed 10 cm inferolaterally to the midline camera port in a pararectus location. The fourth arm of the robot can be used, based on surgeon preference, and would require placement of another 8-mm robotic port approximately 8 cm lateral to one of the pararectus ports and two fingerbreadths above the anterior superior iliac spine, on the same side as the diverticulum (not shown). This will allow placement of a lateral 12-mm assistant port on the side contralateral to the diverticulum approximately two fingerbreadths above the anterior superior iliac spine. This configuration provides the assistant direct access to the region of interest compared with ipsilateral placement of the assistant port, which may limit freedom of motion because of the iliac bone. An additional 5-mm assistant port may be placed in the upper abdomen on the side contralateral to the diverticulum. It should be situated in a triangulated distance of 8 cm from the camera port and paramedian robotic port (see Fig. 132.10A).

After placement of the ports, the robotic is docked either on the side of the patient for the Xi model or in between the legs for the Si model.

Both LBD and RBD begin with an incision of the peritoneum overlying the diverticulum, which can be identified with the aid of either selective catheterization and filling or cystoscopic transillumination (Fig. 132.11). For larger or multiple diverticula, the bladder can be mobilized by incising the peritoneum lateral to the obliterated umbilical ligament bilaterally, dividing the urachus, and then “dropping” the bladder posteriorly to enter into the space of Retzius. The 10-mm LigaSure device (ValleyLab, Boulder, CO) can be used during LBD, and a combination of monopolar and bipolar cautery instrumentation is employed during RBD.

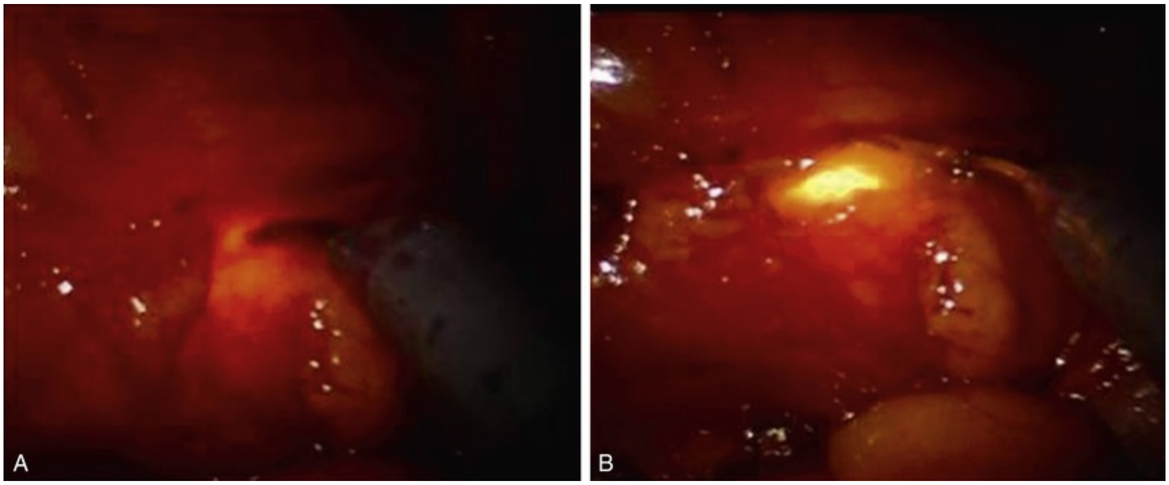

FIG. 132.11 Identification of diverticulum during minimally invasive diverticulectomy. (A) Cystoscopic illumination of diverticulum with flexible cystoscope within the diverticular neck (scissors point to center of diverticulum). (B) Cystoscope repositioned to selected point of bladder entry, anterior to the diverticular neck with ample margin.

Peridiverticular adhesions are transected and the diverticulum is dissected down to its neck (Fig. 132.12A). The extravesical surface of the neck of the diverticulum is circumscribed, either with a monopolar hook during LBD or monopolar scissors during RBD (see Fig. 132.12B). Traction can be applied to the diverticulum sac to facilitate dissection and resection using either robotic Prograsp forceps for RBD or atraumatic bowel grasping forceps for LBD (see Fig. 132.12C). The incision is carried through the wall of the bladder enabling complete excision of the diverticulum. Constant vigilance is required to prevent injury to the ureter or ureteral orifice. In some cases, this may require careful dissection of the ureter off the external surface of the diverticulum. The diverticulum once detached from the bladder is placed in an EndoCatch (Covidien, Mansfield, MA) specimen bag.

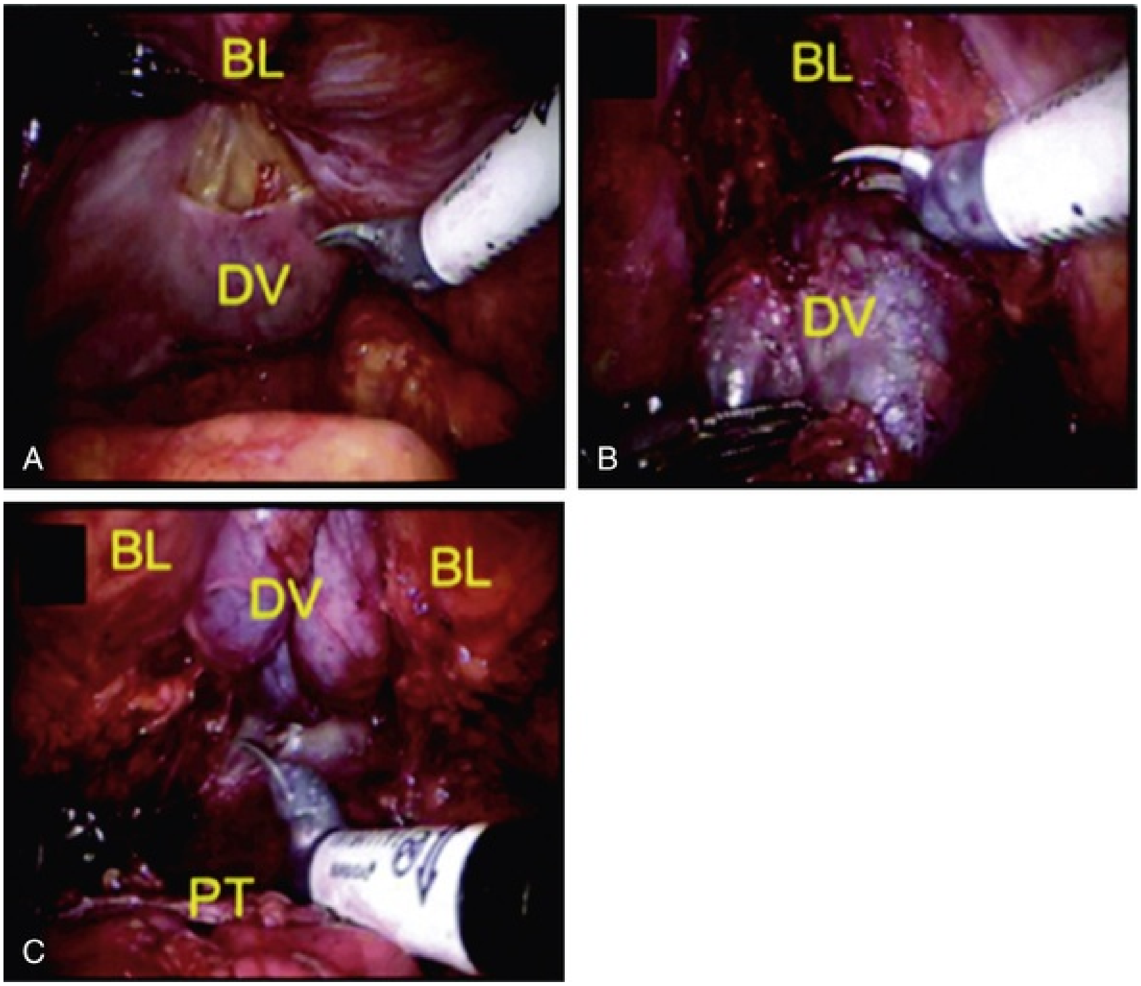

FIG. 132.12 Extravesical robotic bladder diverticulectomy. (A) Distension of diverticulum allows identification from transperitoneal view. Peritoneum overlying diverticulum in vicinity of the neck is incised. (B) Diverticulum is dissection free of peridiverticular connective tissue adhesions down to its neck. An incision is made circumferentially around the neck, beginning anteriorly. (C) Anterior traction placed on the diverticulum allows circumferential incision, seen here on its posterior neck. (Modified from Abreu AL, Chopra S, Dharmaraja A, et al. Robot-assisted bladder

diverticulectomy. *J Endourol* 28[10]:1159–1164, 2014.)

If necessary, a transvesical approach can be employed. After the bladder is dropped, the bladder is opened at its midline. To maintain the pneumoperitoneum, the Foley catheter is plugged externally. The diverticulum mouth is identified, and the diverticulum is pulled into the bladder; inversion can be facilitated by pushing inward on the extravesical surface of the diverticular sac while simultaneously grasping and pulling on the inner mucosal surface from within the bladder. Once inverted, the mucosal lining the neck of the diverticulum is circumscribed, and the incision is carried deeper to allow detachment of the diverticulum from the bladder wall.

In either approach, the bladder wall defect, including the site of diverticular resection and, for the transvesical approach, the site of cystotomy is closed in two layers with 2-0 polyglactin suture. The bladder may be hitched anteriorly to aid in visualization of the defect. During LBD, freehand intracorporeal suturing can be employed. Alternatively, an Endo Stitch device (Covidien, Mansfield, MA) can be used as a suturing aid. An Endo GIA stapler (Covidien, Mansfield, MA) can also be used for excision; however, this carries with it the theoretical risk for bladder stone formation (Kerbl et al., 1993). The bladder is filled to ensure watertight closure. If needed, ureteral reimplantation secondary to reflux, obstruction, or iatrogenic injury is performed as described in the following section. The peritoneum may be reconstituted to recompartmentalize the intraperitoneal and extraperitoneal spaces.

A pelvic drain is placed via one of the trocar sites to avoid an unnecessary additional incision. It is secured to the skin with nonabsorbable suture and placed to self-suction. The pneumoperitoneum is released. The specimen is extracted through an extension of the midline camera-port incision. The fascia of the extraction site and 12-mm assistant port are closed with figure-of-eight 0-polyglactin suture. The skin incisions are closed.

The extraperitoneal approach to LBD involves similar principles as used for the transperitoneal LBD. The extraperitoneal space is first accessed by making an incision 2 cm below the umbilicus and carried through the fascia and linea alba. Blunt finger dissection is used to develop the extraperitoneal space. A dilating balloon inserted into this space can be used to further develop this space. A Hasson port is then placed into this location after which insufflation with CO_2 is used to establish the preperitoneal and retropubic space. Two additional ports, either 5 mm or 12 mm, are placed in the pararectus location inferior to the infraumbilical incision. An additional assistant port (5 mm or 12 mm) may be placed as necessary in the midline between the pubic symphysis and the umbilicus, below the camera port.

LESS has been demonstrated as an approach to diverticulectomy with excellent cosmetic outcomes (Roslan et al., 2012a; Stolzenburg et al., 2011). After single-site access in the transabdominal approach, the operation follows the same basic steps as described earlier for LBD and RBD (Stolzenburg et al., 2011). During transvesical single-site diverticulectomy, the procedure begins with cystoscopy-guided placement of a single-port access device transvesically, followed by the establishment of pneumovesicum (Roslan et al., 2013). The diverticular neck is circumscribed with a monopolar scissors or hook, and the diverticulum is excised. Retraction can be aided by transurethral and/or cystoscopic instrumentation. The defect is subsequently closed, and the specimen is extracted (Roslan et al., 2013).

Postoperative Care and Complications

The Foley catheter is kept to drainage for approximately 1 week postsurgery to allow for adequate healing of the bladder closure. Output from the pelvic drain is monitored because high output may indicate a urinary leak. If the output is low and there is adequate urine output from the Foley catheter, the drain may be removed, typically 48 hours after surgery. Some surgeons may opt to measure a drain fluid creatinine to confirm the integrity of the bladder closure. Before outpatient removal of the Foley catheter, a cystogram should be performed to confirm the absence of contrast extravasation; periprocedural antibiotics are optional to reduce the risk for transient bacteremia.

Complications after bladder diverticulectomy are similar for both open and minimally invasive techniques. The most common complication is urinary extravasation, which may manifest only as high fluid output from the pelvic drain or symptomatically with abdominal pain and fever secondary to an infected urinoma; if performed via a transperitoneal approach, urinary extravasation may present with ileus and electrolyte abnormalities. If still present, a drain serum creatinine can be measured to confirm leak. Cross-sectional imaging can be performed to characterize the degree and location of extravasation. If asymptomatic, the Foley catheter and pelvic drain should be left in place to facilitate healing. Symptomatic presentation may require placement of a percutaneous drain. A drain study and cystogram should be performed before removal of the drain and Foley catheter. Persistence of a urinary leak despite these measures may require placement of percutaneous nephrostomy tubes.

Ureteral injury sustained during diverticular dissection may go unrecognized until the postoperative period, at which time it may present as acute kidney injury or with symptoms of urinary extravasation (e.g., fever, abdominal pain, ileus, electrolyte abnormalities) or flank pain. Excretory urography, and if necessary retrograde imaging, should be performed to confirm and characterize the ureteral injury, visualize hydronephrosis, and identify the presence of a urinoma, which may require percutaneous draining. An attempt at retrograde stent placement should be undertaken; if this fails, a percutaneous nephrostomy should be placed with plans for delayed ureteral repair. Other complications include urinary tract infection, urinary fistula formation, bladder spasms, wound infection, and bowel injury.

Outcomes

Open surgery remains the gold standard for management of bladder diverticula, although increased experience with minimally invasive techniques has enabled use of these strategies for treatment of even complex bladder diverticula, including those that are large in size or multiple in nature (Khonsari et al., 2004).

The majority of comparisons to open surgery are in the form of single-institutional series. Porpiglia et al. studied perioperative outcomes in 12 patients undergoing sequential transurethral resection of the protate followed by transperitoneal LBD versus 13 patients undergoing conventional open diverticulectomy and transvesical prostatectomy (Porpiglia et al., 2004). Diverticula between groups were similar in size and position, and prostatic adenomas were similar in volume. Although operative time was significantly longer in the minimally invasive group (240 vs. 136 minutes), blood loss, postoperative pain, and hospital length of stay was significantly less compared with open surgery. No complications were noted with either approach, and postoperative urinary flow rates were equivalent (Porpiglia et al., 2004).

A case series involving 13 patients who underwent transperitoneal LBD without simultaneous management of bladder outlet obstruction revealed only one postoperative complication in the form of extravasation from the suture line that resolved with conservative management (Abdel-Hakim et al., 2007). In those patients who had diverticular disease secondary to BPH, TURP was successfully performed shortly after LBP without complications. Postoperative follow-up at 3 months revealed significant improvement in International Prostate Symptom Score (IPSS) and uroflowmetry; a normal postvoid residual urine volume was appreciated in all cases. Additionally, no patients had experienced urinary tract infection after their procedure (Abdel-Hakim et al., 2007). Sequential holmium laser enucleation of the prostate and laparoscopic extraperitoneal bladder diverticulectomy has also been performed with favorable outcomes (Shah et al., 2006). As such, laparoscopic bladder diverticulectomy has been shown to be a safe and effective alternative to open diverticulectomy and may in fact be associated with decreased hospital stay.

Robotic bladder diverticulectomy has also been demonstrated to be effective, with excellent perioperative outcomes and hospital stays approximating 2 to 3 days (Abreu et al., 2014; Altunrende et al., 2011; Davidiuk et al., 2015; Eyraud et al., 2013; Kural et al., 2009). A study of 10 patients undergoing transperitoneal RBD using either an extravesical or transvesical approach revealed a median estimated blood loss of 75 mL and operative time of 210 minutes. At 18-month follow-up, median IPSS had decreased by 57% (Abreu et al., 2014). Of note, one (10%) major complication was noted in this series in a patient who had undergone concomitant RBD and robotic suprapubic prostatectomy. Eyraud et al. reviewed 13 series of RBD involving a total of 44 patients (Eyraud et al., 2013). Median size of the treated diverticulum was 8.3 cm. The authors noted favorable operative times (median 186 minutes) and blood loss (86 mL) as well relatively short median hospital length of stay of only 2 days. Time to removal of the Foley catheter ranged between 7 and 14 days and was similar to that reported in open series. Two patients experienced a postoperative complication; one involved development of a urinary tract infection managed with antibiotics, and the other was a urinary leak across the suture lines requiring longer duration of catheterization (Eyraud et al., 2013). Davidiuk et al. more recently reported on 16 consecutive patients who underwent RBD (Davidiuk et al., 2015). Median operative time ranged between 149 and 228 minutes, and no major complications were seen in their cohort at 30-day follow-up. Additionally, significant reductions in postvoid residual volume (458 mL preoperatively to 214 mL postoperatively) and American Urological Association Symptom Score (AUASS) (18 preoperative to 7 postoperatively) were observed (Davidiuk et al., 2015).

When considered in aggregate, the published literature on RBD indicates the ability to achieve favorable outcomes with low risk for complications and operative times shorter than that seen with laparoscopic techniques.

Ureteral Reimplantation

Description

Ureteral reimplantation in adults may be required for a multitude of reasons in both the acute and elective setting. More urgent circumstances arise in the context of either trauma situations, in which case an open approach to repair is preferable, or with recognized iatrogenic injury during pelvic and retroperitoneal procedures (Dowling et al., 1986; Vakili et al., 2005), for which open or minimally invasive attempts at reconstruction may be employed depending on the approach of the index procedure and the magnitude of injury.

Elective procedures aimed at restoring continuity between the ureter and bladder occur most frequently in the setting of ureteral stricture disease or unrecognized iatrogenic ureteral injury with delayed clinical manifestation (Dowling et al., 1986; Roberts et al., 1998; Vakili et al., 2005; Weinberg et al., 1987). Less often in adults is ureteral reimplantation performed for primary vesicoureteral reflux. Ureteral reimplantation also may be performed in a single-stage fashion as part of a planned procedural intervention for separate indication, such as bladder diverticulectomy, partial cystectomy, or distal ureterectomy for upper tract urothelial carcinoma.

Described here are approaches to ureteral reimplantation primarily in the context of nonmalignancy states.

Evaluation and Surgical Indications

The importance of careful intraoperative and, in instances of elective repair, preoperative evaluation cannot be overstated as a successful reimplantation of the ureter is highly contingent on a tension-free anastomosis with the bladder (Dowling et al., 1986); as such, accurate characterization of the length and location of the defect is necessary.

In the acute setting, direct inspection of the ureter allows for an accurate assessment of the magnitude of injury, in which case intraoperative imaging may not be required. Careful attention should be placed on the health of both the ureteral tissue and periureteral blood supply. Information on the mechanism of injury helps inform judgement regarding ureteral viability as debridement of tissue with gross normal appearance may be required, especially in cases of thermal or high-velocity projectile injury. When encountering incomplete transection or ureteral contusion, an intraoperative retrograde pyelogram may be performed to evaluate for the presence, magnitude, and location of extravasation. Alternatively, methylene blue may be injected into the ureter directly from a proximal location.

For elective ureteral reimplantation, both antegrade and retrograde imaging should be utilized to properly characterize the length and location of the diseased ureteral segment (Fig. 132.13). Antegrade imaging may involve use of CT urography, although if a nephrostomy tube is in place, antegrade nephrostogram can be performed (Fig. 132.14). Multiplicity of diseased ureteral segments should be noted on imaging as this would increase the overall length of the defect despite normal appearing intervening segments.

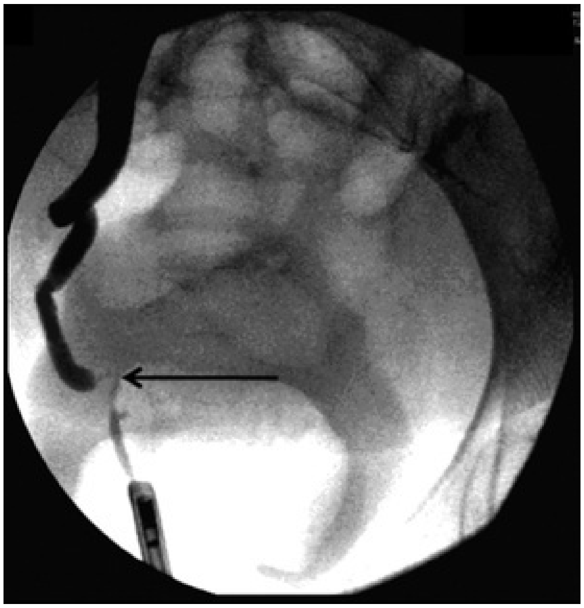

FIG. 132.13 Retrograde pyelogram demonstrating an abrupt cutoff of the right distal ureter consistent with distal ureteral injury sustained during hysterectomy performed 8 days earlier *(arrow).* (Modified from Kalisvaart JF, Finley DS, Ornstein DK. Robotic-assisted repair of iatrogenic ureteral ligation following robotic-assisted hysterectomy. *JSLS* 12[4]:414–416, 2008.)

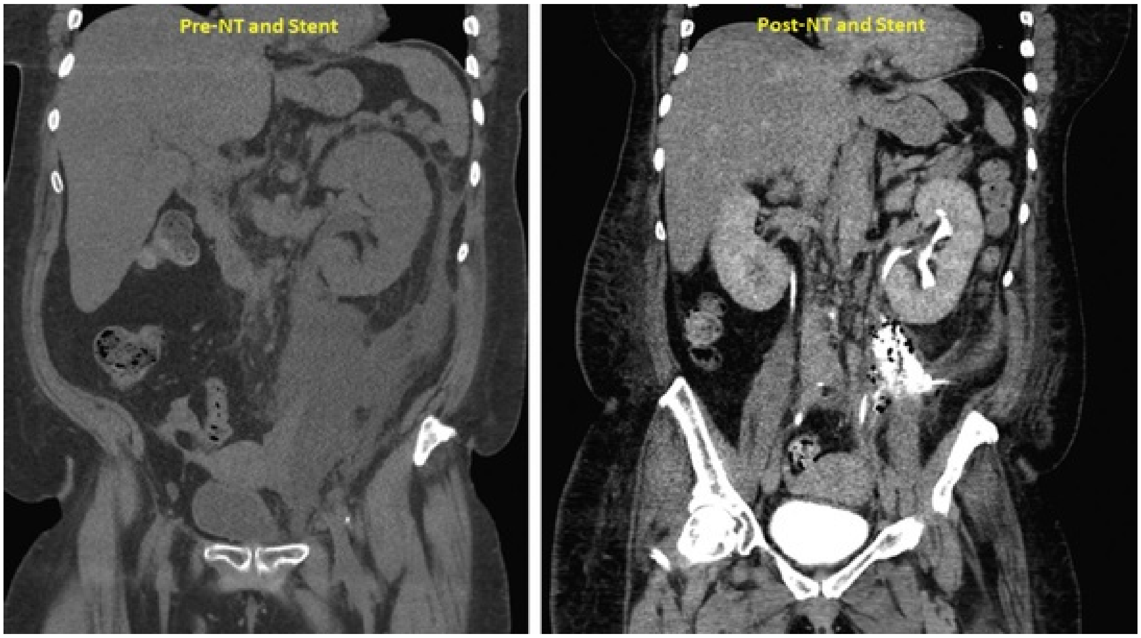

FIG. 132.14 Delayed presentation of ureteral injury sustained during ureteroscopy. *Left,* Large periureteral fluid collection consistent with urinoma. *Right,* Despite 6 weeks of ureteral stent placement and percutaneous drain, persistence of extravasation is seen on excretory phase of computed tomography urography.

Ureteral stricture disease may occur secondary to the presence of an impacted stone, history of pelvic or abdominal radiation, or chronic infection or inflammation. It is important that malignancy is ruled out before intervention. This may involve urine cytology and, in high-risk individuals (e.g., smoking history, older age), endoscopic evaluation with biopsy. Additionally, a resected stricture specimen may be sent for intraoperative frozen section.

Evidence of renal atrophy on imaging, particularly in the setting of chronic obstruction, may require a nuclear renography to be performed to not only document obstruction, but also to evaluate renal function. In cases of severe obstruction, a nephrostomy tube may be placed to enable more accurate characterization of renal function after relief of obstruction. Ureteral reimplantation should not be performed if poor function of the ipsilateral renal unit is demonstrated.

In circumstances in which a ureteral stent had been placed for ureteral contusion or partial ureteral transection sustained during trauma or iatrogenic injury, retrograde pyelography or CT urography should be performed before removal of the stent. If retrograde pyelogram is performed, the stent should be exchanged for a guidewire to maintain continuity across the bladder and ureter.

The presence of urinary extravasation despite adequate duration of stent placement indicates persistence of ureteral injury and is an indication for ureteral reimplantation (see Fig. 132.14). In such cases, a ureteral catheter should be advanced into the renal pelvis over a guidewire and a retrograde pyelogram performed with gradual withdrawal of ureteral catheter during contrast injection. This will enable complete opacification of the ureter and help better characterize the extent and location of injury.

Surgical Technique

The approach to ureteral reimplantation depends partly on the indication for which it is being performed. As the majority of cases in adults are for ureteral injury, stricture disease, or reimplantation during partial cystectomy or diverticulectomy, dissection of the intramural segment of ureter is generally not necessary (Elliott and McAninch, 2006). Instead, the ureter may be divided proximal to the diseased portion with the distal stump tied. For cases in which there is concern over inadequate ureteral length, advancement flaps constructed from the bladder wall offer a means to establish a tension-free ureterovesical anastomosis.

A nonrefluxing anastomosis is generally not necessary in adults, as vesicoureteral reflux is rarely the primary indication for surgery. Several studies confirm that use of a refluxing anastomosis does not necessarily place individuals at risk for accelerated decline in renal function or risk for stenosis when compared with nonrefluxing anastomoses (Stefanovic et al., 1991). Whether a difference in infectious complications exists remains understudied, although long-term studies in adults undergoing a refluxing anastomosis do not seem to indicate increased risk for infection (Wenske et al., 2013).

Irrespective of the technique used, several cardinal principles must be obeyed to optimize the chance for a successful postoperative outcome. The ureter should be delicately manipulated to minimize devascularization injury. In similar regard, a conscious effort should be made during extravesical mobilization of the ureter to preserve the periureteral fibroadipose tissue and avoid excessive skeletonization, which may also compromise the blood supply. The creation of a tension-free ureterovesical anastomosis is also of paramount importance. Primary reimplantation of the ureter into the bladder is generally feasible for defects of the distal ureter up to 4 cm in length. For longer-sized defects of the distal ureter, a psoach hitch and/or Boari flap should be considered to avoid unnecessary stretch on the ureterovesical anastomosis. Renal mobilization and downward nephropexy may also be attempted as this can add up to 5 cm in ureteral length. Lastly, reimplantation of the ureter into the bladder should avoid excessive angulation near its entry into the bladder as this may lead to postoperative obstruction. As a general rule, the ureter should be inserted into the bladder in a path directed toward the bladder neck.

As alluded to earlier, the technique used for ureteral reimplantation depends in part on the clinical circumstances surrounding ureteral injury and the preference of the treating surgeon. Open surgery is preferred for trauma situations as this allows direct inspection of the abdomen and pelvis for associated injuries. Iatrogenic injury recognized intraoperatively may be managed using the same approach as the index procedure, although this depends on the comfort of the surgeon and the established surgical setup.

Open Technique

Ureteral Mobilization.

The patient is placed on the operating table in the supine position with the anterior superior iliac spine positioned over the break of the table. The table is placed into slight flexion to facilitate entry into the retropubic space of Retzius (see Fig. 132.5A). The external genitalia and abdomen are sterilely prepped and draped to just above the level of the umbilicus. A 16-Fr catheter is placed into the bladder on the sterile field.

A midline infraumbilical incision is made down to the level of the pubic symphysis (see Fig. 132.5B). The subcutaneous tissue is divided with electrocautery down to the level of the rectus fascia. The rectus fascia is divided in the midline at the linea alba along the length of the incision. The underlying bellies of rectus abdominus muscles are subsequently split, permitting access to the transversalis fascia, which is divided the length of the incision to allow entry into the space of Retzius. Care should be taken to avoid inadvertent entry into the peritoneal cavity.

The bladder is identified through palpation of the Foley catheter balloon, and the lateral pelvic gutters are developed with blunt dissection using a sponge stick, sweeping the perivesical fat medially.

Adequate exposure of the great pelvic vessels will facilitate identification of the ureters. The external iliac artery can be traced proximal toward the bifurcation of the common iliac artery, where the ureter is identified as it crosses over from lateral to medial (Fig. 132.15A). Alternatively, the ureter may be localized as it courses underneath the obliterated umbilical artery near its origin off of the proximal internal iliac artery. Using a right-angle clamp, the ureter is dissected circumferentially, allowing for placement of a vessel loop. Extravesical dissection of the ureter is then commenced caudad and cephalad taking care to avoid overskeletonization.

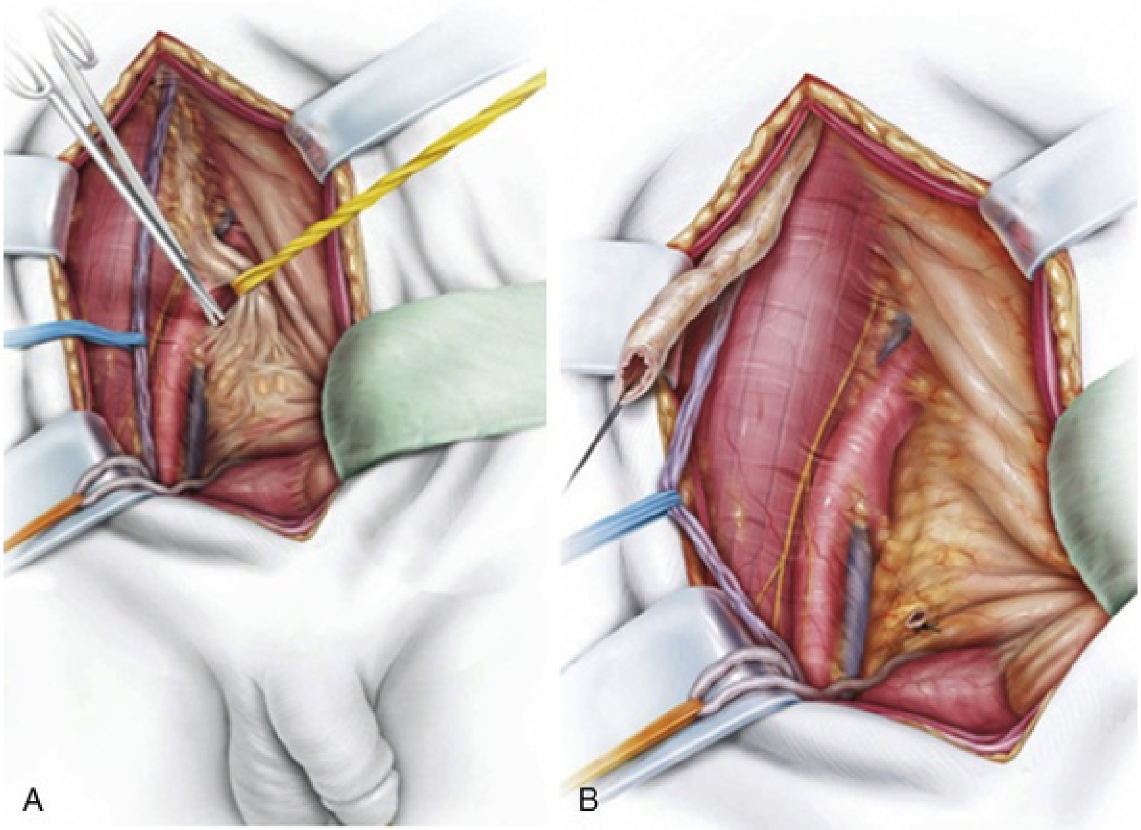

FIG. 132.15 Ureteral mobilization. (A) The ureter is identified as it crosses over the bifurcation of the iliac vessels and subsequently mobilized both cephalad and caudad, ensuring preservation of periureteral tissue. (B) The ureter is transected above the diseased segment with the distal ureter tied or clipped. Stay sutures are placed on the transected proximal ureter. (Modified from Stein R, Rubenwolf P, Ziesel C, et al. Psoas hitch and Boari flap ureteroneocystostomy. *BJU Int* 112[1]:137–155, 2013.)

In cases of ureteral stricture disease or iatrogenic injury, the diseased ureteral segment is identified and resected. Before transection, the distal ureteral stump is sealed using a metal clip. A metal clip may also be placed across the ureter proximal to the diseased area as this will allow for passive ureteral distension and aid in subsequent reimplantation. A 4-0 poliglecaprone suture tag is placed on the end of the ureter at the 6 o'clock position to aid with manipulation (see Fig. 132.15B). In the case of stricture disease, a margin of the transected ureter is sent for frozen-section analysis to rule out malignancy.

Bladder Mobilization.

Dissection within the lateral pelvic gutters is carried out superiorly, enabling cephalad displacement of peritoneal reflection off the bladder dome. The bladder should be disengaged from the overlying peritoneal reflection as much as possible using a gentle sweeping motion of the sponge stick in a cephalad-medial direction. This may involve transection of the ipsilateral medial umbilical ligaments and urachus at the dome of the bladder (Fig. 132.16).

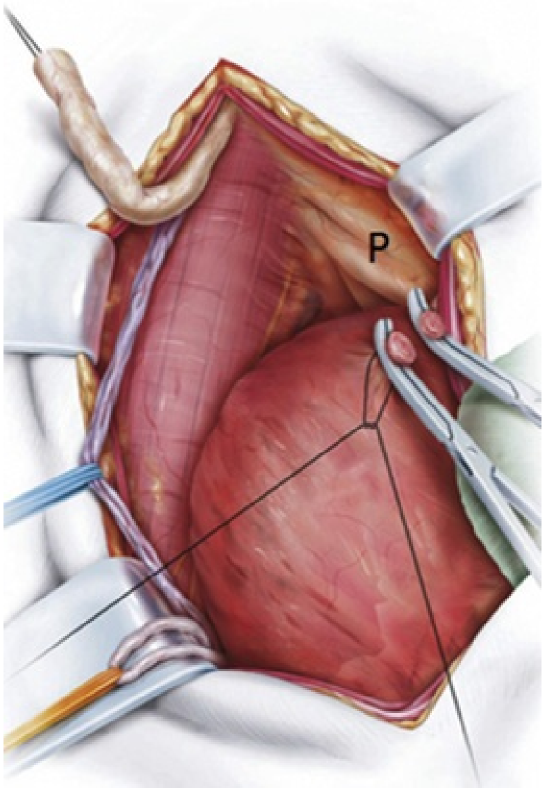

FIG. 132.16 Bladder mobilization. The bladder is mobilized in the extravesical space, pushing the peritoneal reflection *(P)* off the dome. This may involve transection of the ipsilateral medial umbilical ligament (and potentially the urachus). (Modified from Stein R, Rubenwolf P, Ziesel C, et al. Psoas hitch and Boari flap ureteroneocystostomy. *BJU Int* 112[1]:137–155, 2013.)

If a refluxing anastomosis is planned, the bladder does not require the same level of mobilization as is needed for a nonrefluxing anastomosis; this is because the ureter will be reimplanted into the posterior bladder dome, a location more accessible than that needed for nonrefluxing, tunneled anastomoses.

At this point, the feasibility of performing a primary ureteroneocystostomy should be assessed by approximating the ureter to the decompressed bladder dome and ensuring that no tension is present. In some cases in which the ureteral length falls short, the ureter can be mobilized further cephalad, although this increases the risk for devascularization and future stricture disease.

If a primary ureteroneocystotomy is pursued, multiple techniques for reimplantation may be implemented via both an extravesical and intravesical approach in either a refluxing or nonrefluxing fashion.

Nonrefluxing Ureteral Reimplantation—Extravesical Approach (Modified Lich-Gregoir)

The bladder is partially distended with 150 mL of sterile water. This aids not only in reimplantation, but also dissection of the bladder off the overlying peritoneal attachments. Ideally, the bladder should be mobilized enough so such that medial retraction of the bladder on the side of the ureteral pathology enables visualization of the native ureterovesical junction. Ureteral reimplantation should occur on the posterior bladder wall in a location superior and medial to the original ureterovesical junction as placement in a more lateral location would risk kinking, particularly during bladder distension.

A transmural cystotomy is made at the anticipated site of the new ureteral orifice (neo-orifice), with the size of the mucosal defect being slightly wider than the caliber of the transected ureteral lumen (Fig. 132.17B). A longitudinal incision is subsequently made in the serosal and detrusor layers of the bladder, sparing the underlying urothelium, with the directionality of this incision aimed toward the bladder neck (see Fig. 132.17A). The detrusor layer is dissected off the underlying urothelium perpendicularly, effectively allowing the creation of a submucosal tunnel via an extravesical approach. The length of the submucosal tunnel should be roughly three to five times the diameter of the ureter to be reimplanted. Inadvertent entry into the urothelium during creation of the tunnel via an extravesical approach may be closed with 4-0 poliglecaprone suture reapproximating the mucosal edges.

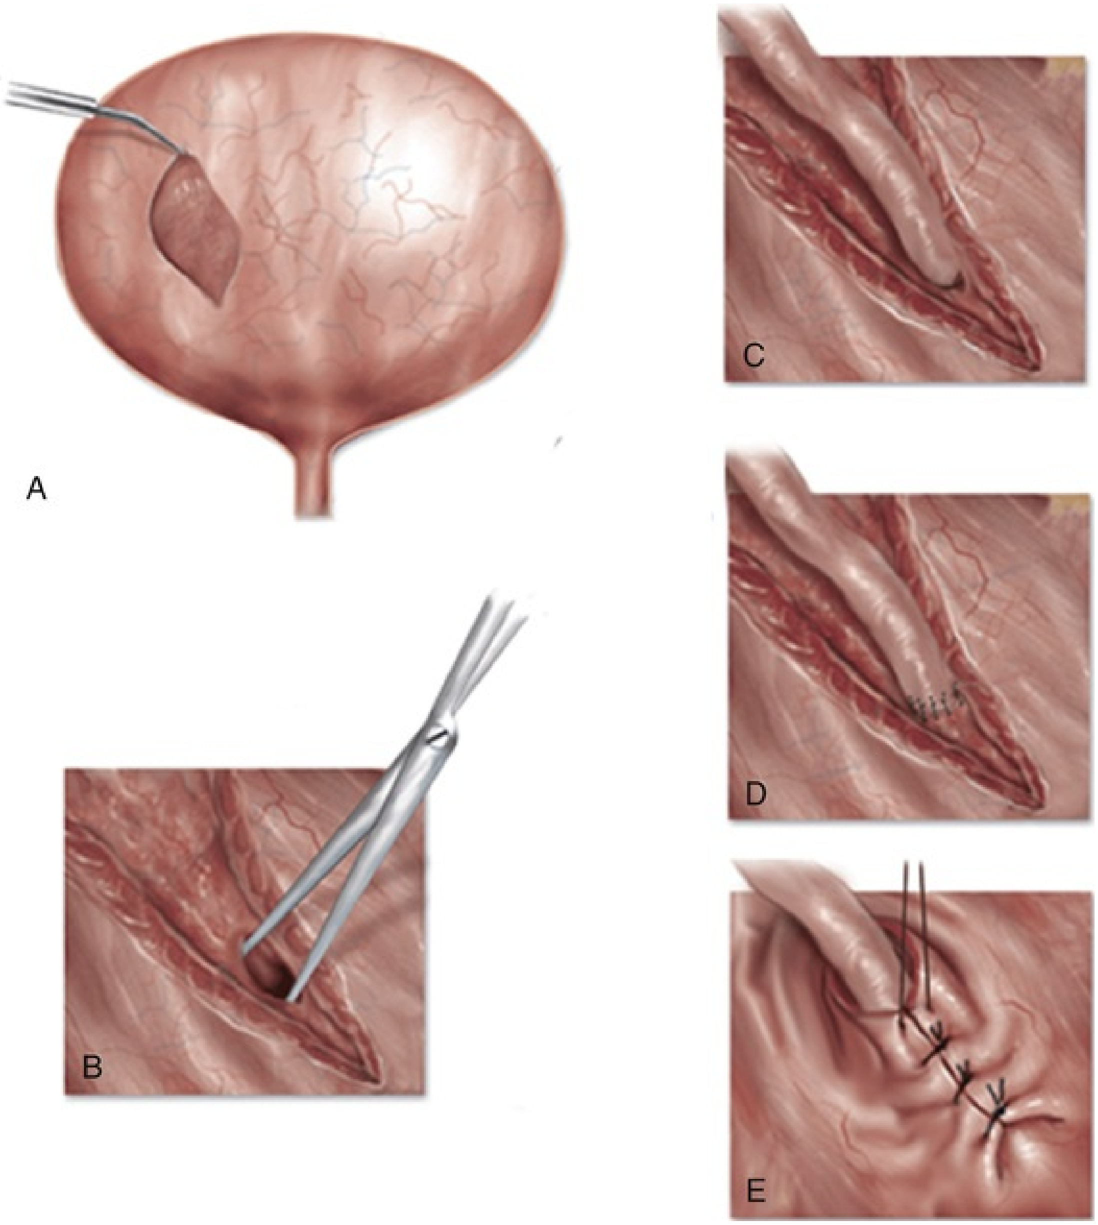

FIG. 132.17 Extravesical, nonrefluxing (tunneled) ureteral reimplant—modified Lich-Gregoir. (A) The detrusor is incised extravesically, sparing the underlying mucosa, to create a submucosal tunnel. (B) A mucosal defect is created at the end of the tunnel wide enough for ureteral reimplantation. (C) The ureter placed in the submucosal tunnel. (D) The distal end of the ureter is spatulated and anastomosed to the neo-orifice. (E) The detrusor muscle is closed to create the antirefluxing submucosal tunnel.

In preparation for reimplantation of the ureter, the distal end of the transected ureter is excised and the new distal end is spatulated anteriorly using sharp tenotomy scissors. The apex of the spatulated ureter is anchored to the mucosa of the neo-orifice at the 12 o'clock position using 4-0 poliglecaprone suture (see Fig. 132.17C). It is critical that sutures placed through the ureter are transmural and those placed through the bladder incorporate the edges of the bladder mucosa and some of the detrusor layer; this ensures proper apposition of the mucosal surfaces. Additionally, the sutures should be placed such that the knots fall external to the anastomosis. The posterior ureter is then anchored to the neo-orifice on the bladder at the 6 o'clock position after which sutures are placed circumferentially in an interrupted fashion to complete the ureterovesical anastomosis (see Fig. 132.17D). Before completion of the anastomosis, a 6-Fr by 26- or 28-cm indwelling double pigtail stent is placed retrograde across the anastomosis.

The anastomosed ureter is placed within the submucosal tunnel over which the serosal-detrusor flaps, created previously to generate the submucosal tunnel, are closed using 2-0 polyglactin suture (see Fig. 132.17E).

A large-bore Foley catheter is placed, and the bladder is filled with 200 mL of sterile water to test the adequacy of the anastomosis. A pelvic drain is placed in the vicinity of the anastomosis and brought out to the skin through a separate stab incision. It is secured to the skin with nonabsorbable suture and placed to self-suction. The fascia and skin are closed in the standard fashion.

Nonrefluxing Ureteral Reimplantation—Transvesical Approach (Modified Politano-Leadbetter)

The bladder is mobilized in a manner similar to the extravesical approach. With the bladder partially distended, a midline cystotomy is made along the anterior surface to gain intravesical access. A suction device is used to aspirate fluid from the bladder as the cystotomy is created.

The location for the neo-orifice should be selected such that it is situated on the posterior bladder wall superior and medial to the native ureteral orifice. Once this site has been determined, the bladder mucosa is circumferentially scored and a mucosal defect generated. The diameter of the neo-orifice should be slightly larger than the diameter of the ureter to be reimplanted (approximately 1.5 cm). A submucosal tunnel is subsequently developed using Metzenbaum scissors, starting at the neo-orifice. The tunnel should be oriented longitudinally in the direction of the bladder neck, with the length of this tunnel being 3 to 5 times the caliber of the ureteral lumen.

Once a submucosal tunnel of appropriate length has been generated, the Metzenbaum scissors are exchanged for a right-angle clamp. The beak of the right-angle clamp is directed posteriorly, and an incision is made through the posterior bladder wall onto the clamp; this will serve as the new entry site for the ureter into the bladder. The location of this new ureterovesical junction should be cephalad and medial to the native ureterovesical junction as this will allow the ureter to be oriented almost longitudinally as it courses through the submucosal tunnel. The right-angle clamp is advanced through the posterior bladder wall and used to grasp the ureteral stay sutures (Fig. 132.18B). The ureter is delivered through the submucosal tunnel and out of the neo-orifice into the bladder.

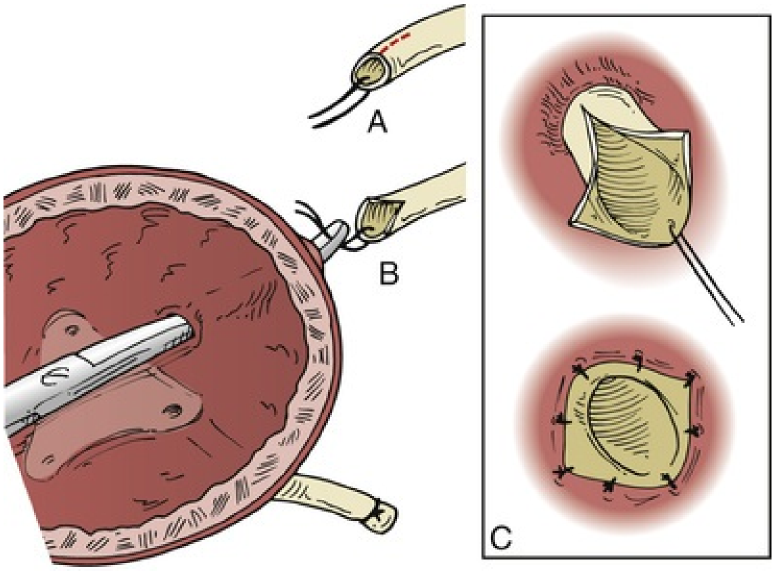

FIG. 132.18 Transvesical, nonrefluxing (tunneled) ureteral reimplant—modified Politano-Leadbetter. (A) Stay sutures are placed on the distal end of the transected ureter. (B) The neo-orifice is delineated on the intravesical bladder surface, and a submucosal tunnel is created with sharp dissection. A cystotomy is made through the posterior bladder wall, and the ureter is delivered into the bladder, traversing through the tunnel and neo-orifice. (C) The ureter is spatulated anterior and anastomosed in a interrupted fashion to the neo-orifice. (Modified from Yeomans ER, Hoffman BL, Gilstrap 3rd LC, Cunningham FG. *Cunningham and Gilstrap's operative obstetrics*. 3rd ed. McGraw-Hill Education; 2017.)

The ureter is spatulated and anastomosed to the mucosa of the neo-orifice with stent placement in a manner similar to that described earlier (Fig. 132.18C).

A large-bore Foley catheter is placed, and the cystotomy is closed in the standard two-layer fashion using 2-0 polyglactin suture. The bladder is filled with 200 mL of sterile water to test the adequacy of closure and anastomosis. A pelvic drain placed in the vicinity of the bladder wall closure and anastomosis is brought out to the skin through a separate stab incision and placed to self-suction. The fascia and skin are closed in the standard fashion.

Refluxing Ureteral Reimplantation—Extravesical Approach

The dome of the bladder is grasped with Allis clamps, and a transmural cystotomy is created in the posterior dome lateralized to the side of ureteral pathology. The diameter of the defect should be wide enough to accommodate the transected ureter.

After excising the distal end of the transected ureter, the new distal end is spatulated anteriorly and reanastomosed to the bladder in a manner similar to that described earlier for the nonrefluxing, extravesical approach (Fig. 132.19).

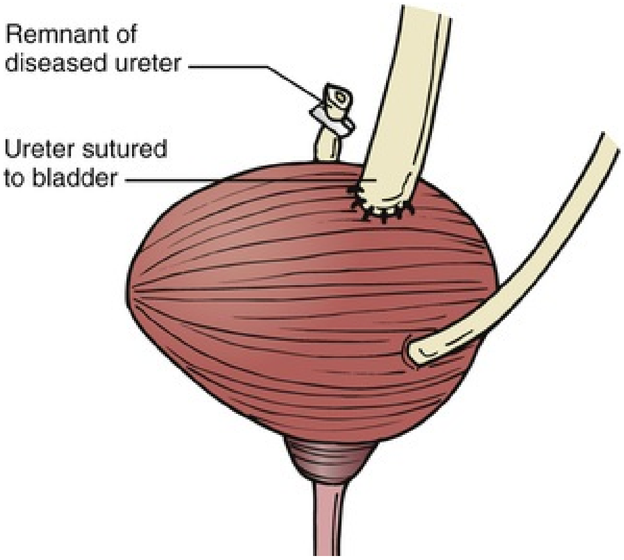

FIG. 132.19 Extravesical, refluxing ureteral reimplant. The healthy transected portion of the proximal ureter is reimplanted into the dome of the bladder.

A large-bore Foley catheter and pelvic drain are placed as described earlier. The bladder should be irrigated to test for adequacy of the anastomosis.

Refluxing Ureteral Reimplantation—Transvesical Approach

With the bladder partially distended, an anterior midline cystotomy is made to gain intravesical access. A Kelly clamp is placed through the cystotomy and directed posteriorly against the posterior bladder dome lateralized to the side of the ureteral pathology. A cystotomy is created over the Kelly clamp large enough to accommodate the transected ureter. The Kelly clamp is advanced posteriorly through the bladder wall defect and used to grasp the stay sutures on the distal end of transected ureter. The ureter is brought into the bladder through the posterior bladder wall defect as the Kelly clamp is withdrawn. This will effectively serve as the new ureterovesical junction and associated neo-orifice.

The ureter once delivered into the bladder is spatulated and anastomosed to the mucosa of the neo-orifice in a manner similar to that described earlier.

A large-bore Foley catheter is placed, and the cystotomy is closed in the standard two-layer fashion using 2-0 polyglactin suture. The bladder is filled with 200 mL of sterile water to test the adequacy of closure and anastomosis.

A pelvic drain placed in the vicinity of the bladder wall closure and anastomosis is brought out to the skin through a separate stab incision and placed to self-suction. The fascia and skin are closed in the standard fashion.

Laparoscopic and Robotic Techniques

Minimally invasive approaches to distal ureteral reconstruction are widely utilized in contemporary practice given extensive accumulated experience that has enabled near-replication of open techniques (Ehrlich et al., 1994; Janetschek et al., 1995; Reddy and Evans, 1994; Schimpf and Wagner, 2008).

A transperitoneal, extravesical approach offers a wide working space and permits creation of both refluxing and nonrefluxing anastomoses. Additionally, the technical feasibility to perform a psoas hitch and bladder advancement flaps using a minimally invasive platform allows experienced surgeons to utilize laparoscopy and robotic surgery for management of longer ureteral defects.

We routinely perform laparoscopic ureteral reimplantation using a three-trocar approach as depicted in Fig. 132.20. Patient positioning and typical port site placement for robotic ureteral reimplant is similar to that employed for bladder diverticulectomy (see Fig. 132.10A). It is important to keep in mind that placement of the assistant ports for robotic reimplantation occurs on the side contralateral to the ureteral pathology as this allows the assistant more direct access.

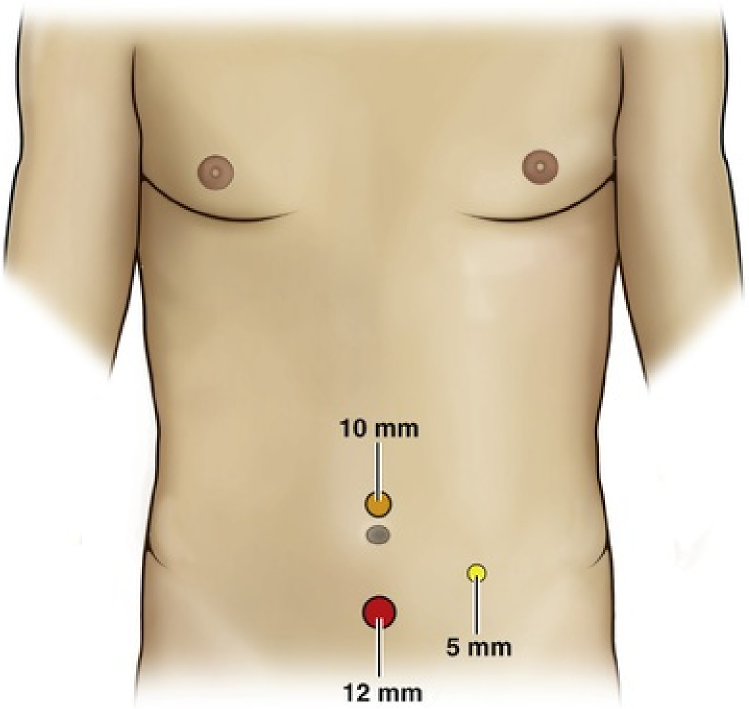

FIG. 132.20 Port placement for laparoscopic ureteral reimplantation (left-sided). Trocar placement for left ureteral reimplantation includes a 10-mm umbilical camera port and a 12-mm working port placed halfway between the umbilicus and the symphysis pubis. A 5-mm working port is placed at the lateral edge of the rectus muscle at the level of the umbilicus on the ipsilateral side of the procedure.

The ureter is identified medial to the obliterated umbilical ligament, and the overlying peritoneum is incised. Alternatively, the parietal peritoneum may be incised more proximally where the ureter courses over the bifurcation of the common iliac artery. The ureter is mobilized caudally toward the ureterovesical junction, preserving periureteric tissue to ensure adequate vascular supply. The ipsilateral vas deferens in males or broad ligament in females may be divided to facilitate identification and exposure of the distal ureter. An incision may also be made lateral to the ipsilateral obliterated umbilical ligament to enter the space of Retzius and allow for medial rotation of the bladder, which remains suspended as the contralateral ligament is kept intact.

The diseased segment of ureter is identified, and a metal Hem-o-lok clip (Teleflex, Morrisville, NC) is placed at this distal edge (if possible), effectively closing off the distal ureteral stump. The diseased segment is then excised. In the case of stricture disease, a margin of the transected ureter is sent for frozen-section analysis to rule out malignancy. A metal clip may be placed on the end of the proximally transected ureter to allow for passive ureteral dilation that can aid in subsequent reimplantation. A 4-0 suture may also be placed at the distal end of the transected ureter to enable atraumatic manipulation.

The bladder is dropped and the space of Retzius accessed in a manner similar to that described earlier for robotic diverticulectomy. The feasibility of a tension-free anastomosis is assessed by approximating the ureter to the ipsilateral dome of a nondistended bladder.

Nonrefluxing Ureteral Reimplantation—Extravesical Approach (Modified Lich-Gregoir)

When performing a extravesical nonrefluxing anastomosis, the location of the proposed tunnel is determined with the bladder filled with approximately 250 to 300 mL of saline. Care should be taken to orient the tunnel in the direction of the bladder neck and select a location that is superior and medial to the native ureterovesical junction, as a more lateral location risks kinking of the ureter during filling. A 5 : 1 tunnel-to-ureteral diameter is maintained. Taking care to avoid perforation of the bladder mucosa, the detrusor muscle is incised to create a sufficient trough. A cystotomy is then made at the distal end of the tunnel to create the neo-orifice.

The ureter is spatulated along its anterior surface, and its apex is anchored to the mucosa of the neo-orifice at the 12 o'clock position using 4-0 poliglecaprone suture. As is the case with the open approach, sutures passed through the ureter are transmural, whereas those passed through the bladder should capture the bladder mucosa and detrusor fibers. Additionally, the knots should fall external to the ureteral lumen. The posterior ureter is then anchored to the neo-orifice on the bladder at the 6 o'clock position after which sutures are placed circumferentially in an interrupted fashion to complete the ureterovesical anastomosis. Before completion of the anastomosis, a 6-Fr by 26- or 28-cm indwelling double pigtail stent is placed retrograde across the anastomosis with the assistance of a guidewire.

The ureter is then placed within the trough, and the detrusor is closed over it, using a series of interrupted 2-0 absorbable sutures (Fig. 132.21) (Gundeti et al., 2008; Hedican et al., 1999; Lakshmanan and Fung, 2000; Reddy and Evans, 1994).

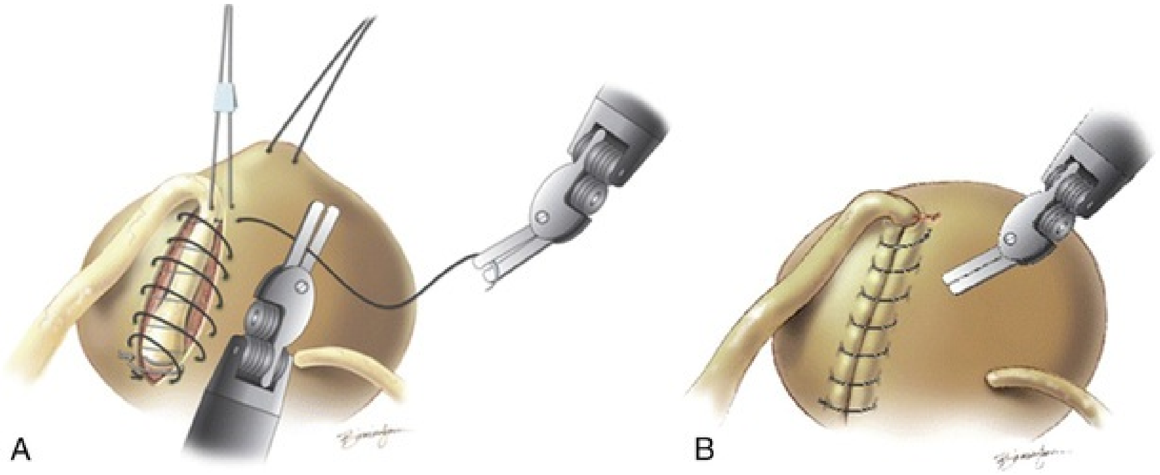

FIG. 132.21 Robotic extravesical nonrefluxing (tunneled) ureteral reimplantation. A tunnel is made in the detrusor muscle for the ureter, completing the antirefluxing mechanism. (A) After anastomosis of the spatulated ureter to the bladder mucosa, detrusorrhaphy is initiated. (B) Completed extravesical reimplantation. (From Gundeti MS, Kojima Y, Haga N, Kiriluk K. Robotic-assisted laparoscopic reconstructive surgery in the lower urinary tract. *Curr Urol Rep* 14[4]:333–341, 2013.)

A large-bore Foley catheter is placed, and the bladder is filled with 200 mL of sterile water to test the adequacy of the anastomosis. A pelvic drain is placed in the vicinity of the anastomosis and brought out through the lateral port. It is secured to the skin with nonabsorbable suture and placed to self-suction. The pneumoperitoneum is released. The fascia of all 12-mm ports are closed with figure-of-eight 0-polyglactin suture. Skin incisions are closed.

Refluxing Ureteral Reimplantation—Extravesical Approach

For cases in which a refluxing reimplantation is planned, the length of ureter needed for a tension-free anastomosis is less than that required for a nonrefluxing anastomosis given the absence of the submucosal tunnel (Seideman et al., 2009). As such, the ureter may be mobilized to a lesser degree.

A new ureteral hiatus is created at the anterior dome of the bladder, slightly lateralized to the site of ureteral pathology. The ureter is spatulated and reimplanted with 4-0 absorbable sutures in an interrupted fashion as described earlier.

A large-bore Foley catheter is placed, and the bladder is filled with 200 mL of sterile water to test the adequacy of the anastomosis. A pelvic drain is placed in the vicinity of the anastomosis and brought out through the lateral port. It is secured to the skin with nonabsorbable suture and placed to self-suction. The pneumoperitoneum is released. The fascia of all 12-mm ports are closed with figure-of-eight 0-polyglactin suture. Skin incisions are closed.

Postoperative Care and Complications

The Foley catheter is kept to drainage for approximately 1 week postsurgery with a cystogram performed before removal to ensure that there is no extravasation. The pelvic drain is removed typically after 48 hours once the output has decreased; a drain creatinine measurement is optional and should be interpreted in the context of the drain output. The ureteral stent is left in place for 6 weeks to provide adequate time for healing of the anastomosis.

Urinary extravasation may complicate the postoperative course of either open or minimally invasive ueteroneocystotomy. This may clinically manifest with fever and abdominal pain, particularly with infection of the urinoma. Ileus or electrolyte abnormalities may occur in the setting of intraperitoneal urinary ascites. Anastomotic leak may result from the lack of a watertight anastomosis or impending ischemia. Excretory urography may help characterize the location and degree of extravasation and the presence of a urinoma that may require percutaneous drainage. Management involves continuing the Foley catheter and ureteral stent to facilitate maximal antegrade drainage. If extravasation occurs after removal of the stent, replacement of the stent is necessary. Placement of a percutaneous nephrostomy tube should be considered for cases refractory to these measures.

Ureteral obstruction is a late complication that can manifest after removal of the stent. It may be detected incidentally on follow-up imaging (e.g., hydronephrosis on ultrasonography) or present with symptoms of flank pain or pyelonephritis. Obstruction typically results from ureteral ischemia because of excessive skeletonization during ureteral mobilization, tension on the ureterovesical anastomosis, the creation of a narrow neo-orifice, inadequate spatulation of the anterior ureter, or prior radiation exposure, which may have perturbed the ureteral blood supply at baseline. Antegrade and retrograde imaging should be used to characterize the size and extent of the strictured segment. Endoscopic interventions to restore patency of the ureteroneocystotomy may be attempted initially, particularly for short-length strictures, although repeat surgery may be necessary for high-grade obstruction (Goldfischer and Gerber, 1997; Hafez and Wolf, 2003; Kwak et al., 1995). Less often, obstruction may occur secondary to reimplantation of the ureter into a more lateral location on the bladder, which risks kinking during bladder distension.

Other complications include development of urinary tract infection, urinary fistula formation, bladder spasms, stent colic, wound infection, and bowel injury.

Outcomes

The open surgical technique for ureteroneocystotomy remains the gold standard for management of distal ureteral disease in adults. Open surgery allows tremendous versality in approach, including the ease of staying entirely extraperitoneal, ability to perform reimplantation via extravesical or transvesical means, option of performing a nonrefluxing or refluxing anastomosis, and the ability to readily integrate procedures such as psoas hitch or Boari flap to ensure a tension-free anastomosis.

Larger studies with long-term follow-up are available primarily for the open surgical approach and confirm the ability to achieve favorable outcomes in the vast majority of individuals with distal ureteral obstruction. Wenske et al. reported on their institutional experience with 100 cases of open distal ureteral surgery performed for ureteral obstruction or injury (Wenske et al., 2013). Primary ureteroneocystotomy, psoas hitch, and Boari flap procedures were performed in 24, 58, and 18 cases, respectively. At a median follow-up of 5 years, 81% of patients with preoperative hydronephrosis had complete resolution. However, 15.3% of patients did require chronic ureteral stent placement to maintain kidney function (Wenske et al., 2013). Complications were rare in this series, with urinary extravasation requiring extended drainage occurring in only 3% of patients.

On the other hand, clinical experience with laparoscopic and robotic ureteroneocystostomy continues to evolve. Small feasibility studies prevail; however, a few larger studies with intermediate-term follow-up data support the efficacy of minimally invasive approaches (Modi et al., 2005; Pompeo et al., 2013; Seideman et al., 2009).

The largest series of laparoscopic ureteral reimplantation in adults was reported by Seideman et al., who described perioperative and functional outcomes in 45 patients undergoing laparoscopic ureteral reimplantation for distal ureteral stricture disease, the mean length of which was 3 cm (Seideman et al., 2009). The authors reported excellent perioperative outcomes, with no cases requiring open conversion, mean blood loss having been 150 mL, and hospital length approximating 3 days. Three patients (6.7%) experienced a low-grade complication, namely urinary extravasation, which were managed conservatively. Success rate, defined as radiographic evidence of no residual obstruction, resolution of symptoms, absence of worsened renal function, and no subsequent intervention, was 96% with 2-year follow-up. Two patients had recurrence of stricture disease, whereas one patient required nephrectomy for chronic pain (Seideman et al., 2009). A more recent series describing laparoscopic ureteroneocystotomy for ureteral injuries after open hysterectomy demonstrated similar findings with a 100% ureteral patency rate on long-term follow-up (Pompeo et al., 2013).

A direct comparison between laparoscopic and open ureteral reimplantation was performed by Rassweiler et al., who studied 10 patients undergoing laparoscopic ureteral reimplantation versus 10 patients treated using conventional open techniques for distal ureteral stricture disease (Rassweiler et al., 2007). The mean length of the ureteral stricture was 2.85 cm in the laparoscopic group versus 2.5 cm in the open group. The authors observed an advantage to the laparoscopic approach as it was associated with lower blood loss, lower analgesic requirements, less time to oral intake, shorter hospital stay, and shorter convalescence time. Additional, procedural success was seen for all 10 patients undergoing laparoscopy, whereas two patients undergoing open surgery had a major postoperative complication, including one who had recurrence of stricture (Rassweiler et al., 2007). Similarly, Simmons et al. (2007) retrospectively compared 12 laparoscopic versus 34 open ureteral reimplantation procedures, demonstrating reduced blood loss and shorter hospitalization associated with laparoscopy. Complication rates and ureteral patency rates were equivalent at a mean follow-up of nearly 2 years (Simmons et al., 2007).

The advent of the robotic platform has generated significant interest recently in robotic-assisted ureteral reimplantation, particularly given the ergonomics of use, enhanced three-dimensional magnification, and availability of articulating joints with six degrees of freedom, which shallows the learning curve for tasks such as intracorporeal suturing. Several authors have reported the feasibility of this approach (Patil et al., 2008; Uberoi et al., 2007; Yohannes et al., 2003a). A recent comparison of robotic ($N = 13$) and laparoscopic ($N = 6$) ureteral reimplantation for benign ureteral stricture disease demonstrated highly comparable perioperative outcomes with intermediate follow-up (Baldie et al., 2012). No major postoperative complications were observed in either arm, although two (15.3%) open conversions were performed in the robotic group and one (16.7%) in the laparoscopic group. Mean operative time (259 vs. 278 min), blood loss (171 vs. 150 mL), and length of stay (2.5 vs. 2.7) was similar between both groups, with all patients having had successful outcomes on both radiographic and clinical assessment at time of last follow-up (Baldie et al., 2012).

Contemporary comparisons between open and robotic reimplantation for benign stricture disease further supports the feasibility and efficacy of the robotic approach as an alternative to open surgery (Isac et al., 2013; Kozinn et al., 2012). In a series by Kozinn et al., 10 patients undergoing robotic distal ureteral reconstruction were compared with 10 matched controls undergoing open surgery (Kozinn et al., 2012). In total, four neocystostomies, four psoas hitches, and two Boari flaps were performed in the robotic arm versus six neocystostomies, three psoas hitches, and one Boari flap performed in the open group. No intraoperative conversion to open surgery was necessary in the robotic cohort. Additionally, blood loss (30.6 vs. 327.5 mL) and hospital length of stay (2.4 vs. 5.1 days) were significantly lower in the robotic group versus the open group with no differences observed in operative time. All patients had successful treatment of their stricture disease based on radiologic and clinical assessment at 24- and 30-month follow-up in the robotic and open groups, respectively (Kozinn et al., 2012). A subsequent comparison of 25 robotic ureteroneocystostomies versus 41 open procedures performed between 2000 and 2010 revealed significantly shorter operative times with the open technique (200 vs. 279 minutes), but less blood loss (100 vs. 150 mL), shorter hospital length of stay (3 vs. 5 days), and less postoperative narcotic pain requirement with the robotic approach. Additionally, no differences were observed in rate of reoperation for disease stricture recurrence (Isac et al., 2013).

Most recently, Elsamra et al. provided a single-institutional review of perioperative outcomes associated with 130 open (N = 25), laparoscopic (N = 85), and robotic (N = 25) cases of ureteroneocystotomy (Elsamra et al., 2014). The authors demonstrated significantly lower operative blood loss and hospital length of stay in patients undergoing minimally invasive versus open surgery, and a numerically higher readmission and 90-day complication rate in the open cohort. These results further support a role for minimally invasive techniques in distal ureteral reconstruction for adults.

LESS surgery has also emerged as a technique with the potential for improved cosmetic outcomes and perhaps reduced pain and convalescence. LESS ureteroneocystostomy has been reported, but larger series are needed to validate the efficacy and safety of the approach (Desai et al., 2009). Roslan et al. reported a case of a LESS ureteroneocystotomy (Roslan et al., 2012b). Khanna et al. reported on three cases of LESS ureteral reimplantation (Khanna et al., 2012). With a median follow-up of 29 months, none of the three patients required revision or had recurrent stricture disease. There are clear technical challenges, and most surgeons reporting on LESS ureteral reimplantations have had broader experiences in LESS nephrectomy and other types of LESS reconstructive surgeries.

Psoas Hitch and Boari Flap

Description

When faced with minimal distal ureteral loss, simple ureteroneocystostomy is sufficient to reestablish urinary continuity. However, more extensive gaps require more complex reconstructive techniques.

A psoas hitch, first described by Zimmerman et al. (1960) and Warwick and Worth (1969), may be utilized to bring the bladder cephalad enough to enable a tension-free anastomosis with the healthy ureteral segment (Ehrlich et al., 1978). If a tension-free anastomosis is not possible using a psoas hitch alone, a Boari flap can be performed in conjunction to bridge the ureteral gap. This situation is most often encountered for ureteral disease extending up to the mid-ureter (Ockerblad, 1947).

The Boari bladder flap was introduced for bridging larger gaps between the ureter and bladder in a canine model in 1894 and in humans in 1947 (Ockerblad, 1947), with the capability of bridging ureteral gaps up to 15 cm in length. Minimally invasive techniques mimicking the open approach have since emerged and expanded the treatment armamentarium for patients with longer segments of ureteral discontinuity. Laparoscopic Boari flap creation was first described in humans in 2001, whereas reports of Boari flap using the robotic platform first emerged in 2008 (Fergany et al., 2001; Fugita and Kavoussi, 2001; Schimpf and Wagner, 2008). The robotic approach can ease the technical burdens of extensive intracorporeal suturing required for Boari flap creation (Allaparthi et al., 2010; Schimpf and Wagner, 2008).

Although these techniques are used more often for defects involving the distal and middle third of the ureter, in select cases, they may be used to bridge defects as high as the proximal ureter and/or renal pelvis, although ureteroureterostomy, transureteroureterostomy, autotransplantation, or ileal ureteral substitution should also be considered in these circumstances.

Evaluation and Surgical Indication

A psoas hitch and Boari flap are indicated when the degree of ureteral loss precludes simple ureteroureterostomy or ureteroneocystostomy. Preoperative evaluation is similar to that described earlier for ureteroneocystostomy and includes antegrade and retrograde urography to estimate the extent of disease and aid in planning for the surgical approach. A small-volume bladder is a contraindication to a psoas hitch and Boari flap. Ultimately, intraoperative findings dictate the need for a Boari flap and/or psoas hitch.

Surgical Technique

Open Technique

Psoas Hitch.

The bladder is mobilized on the side ipsilateral to the ureteral pathology as described for ureteral reimplantation (see Fig. 132.16). The ipsilateral bladder dome is then pulled cephalad and positioned over the ipsilateral psoas muscle above the bifurcation of the common iliac artery. The transected proximal ureteral segment, which has also been mobilized, is placed onto the superior lateral surface of the bladder dome to ensure the ability to create a tension-free ureterovesical anastomosis. Extra mobility of the bladder can be achieved by dividing the round ligament in females or vas deferens in males. If necessary, the bladder may be freed from contralateral perivesical attachments as this may facilitate further cephalad displacement. This may involve ligation of the contralateral superior vesical artery and less often middle vesical arteries and opening of the contralateral endopelvic fascia.

Stay sutures are placed on the anterior dome of the bladder after which an oblique cystotomy is made across the anterior dome at site of its maximum diameter (Fig. 132.22A). The length of this cystotomy should span approximately one-half of the anterior dome as a shorter incision may compromise the degree of cephalad bladder displacement. The surgeon's finger is placed into the bladder and used to displace the ipsilateral posterolateral dome onto the ipsilateral psoas muscle above the common iliac artery bifurcation (see Fig. 132.22B). If further length is necessary, incisions horizontal to the initial oblique cystotomy can be made to release the ipsilateral dome.

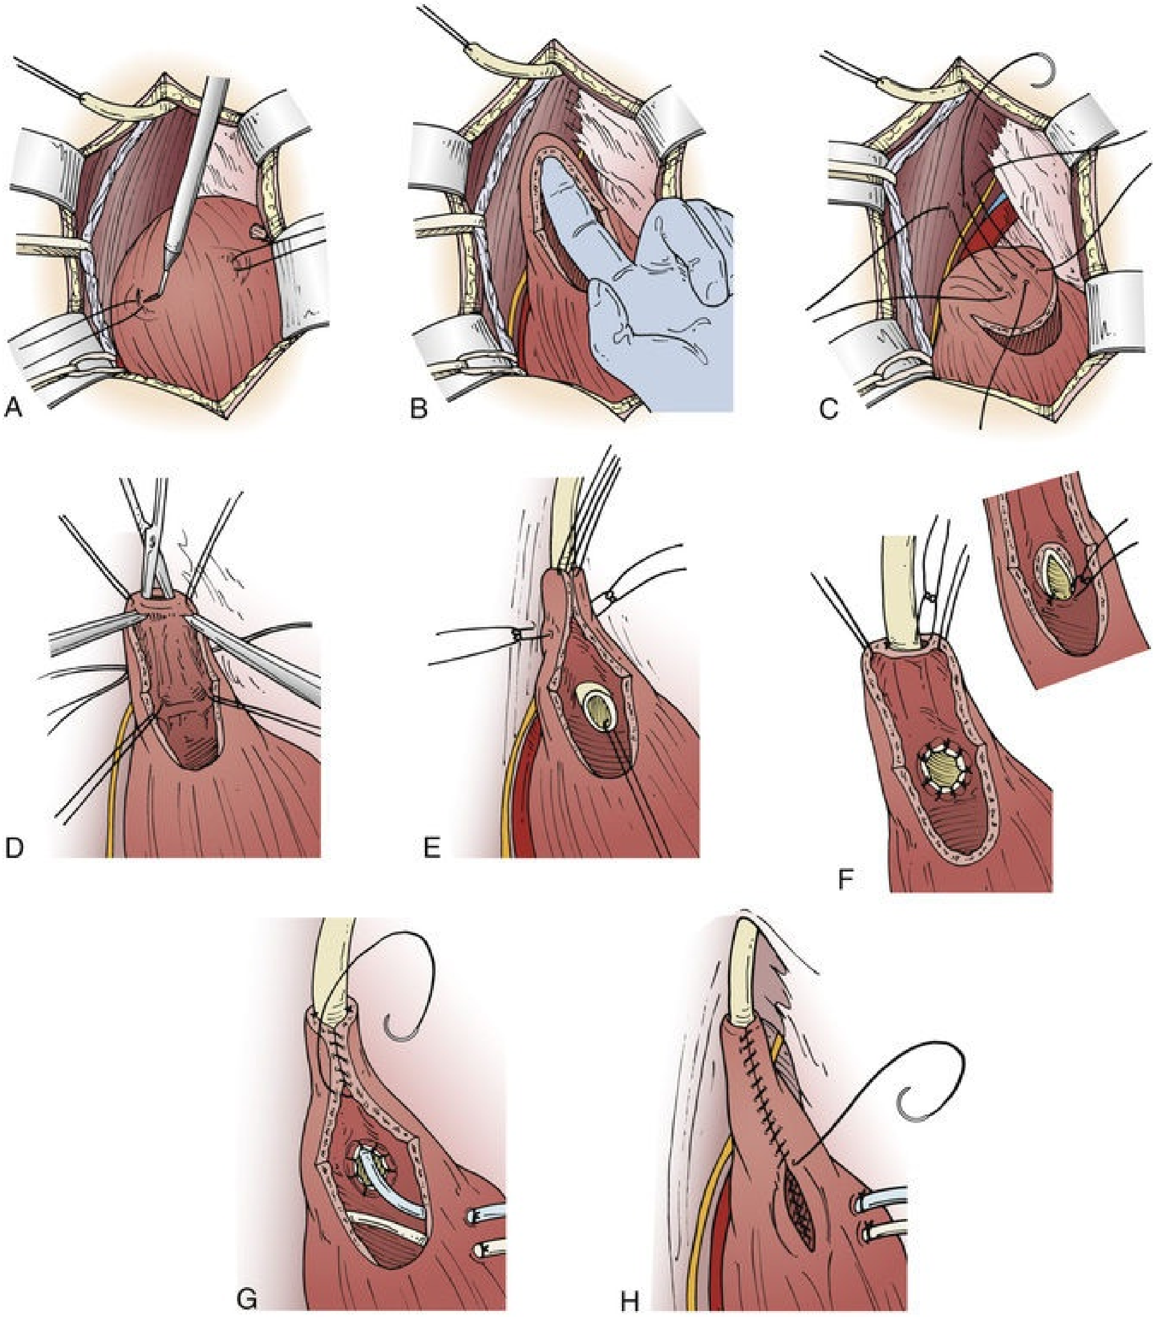

FIG. 132.22 Psoas hitch procedure. (A) A transverse-oblique cystotomy is made on the posterior bladder dome ipsilateral to the ureteral pathology. (B) The bladder dome is displaced cephalad to the ipsilateral psoas muscle. (C) The posterior wall of the bladder dome is sutured to the psoas minor tendon. (D) A tunneled ureteral anastomosis can be created by submucosal dissection toward the neo-orifice. (E) The ureter is delivered through the submucosal tunnel into the bladder. (F) The ureter is spatulated anteriorly and anastomosed to the neo-orifice in an interrupted fashion. The ureter may be loosely anchored to the extravesical surface of the bladder at its point of entry. (G) A ureteral stent is placed and a two-layer closure is commenced by first performing a mucosal closure. (H) The

detrusor is closed. (Modified from Stein R, Rubenwolf P, Ziesel C, et al. Psoas hitch and Boari flap ureteroneocystostomy. *BJU Int* 112[1]:137–155, 2013.)

The extravesical bladder wall surface is anchored to the psoas muscle using four to six 2-0 polyglactin sutures placed through the psoas minor muscle tendon and the bladder detrusor muscle (see Fig. 132.22C). Sutures should be placed superficially through the tendon of the psoas minor parallel to the direction of the muscle fibers so as to minimize the risk for disrupting the genitofemoral nerve, situated superficially on the psoas muscle, or the femoral nerve, located deeper in the belly of the muscle.

Before tying the anchoring sutures, the site for the ureteroneocysostomy should be determined and the ureter delivered into the bladder (see Fig. 132.22E). Ideally, the ureter should be reimplanted on the superior-lateral aspect of the displaced bladder dome segment as this would allow for it to follow its native trajectory and be positioned on a relatively immobile portion of the bladder, reducing the likelihood for kinking.

If a nonrefluxing anastomosis is planned, a submucosal tunnel is generated via either an extravesical or intravesical approach as described earlier (see Fig. 132.22D). Shorter ureteral segments may require creation of a refluxing anastomosis.

4-0 polyglactin sutures are placed extravesically to loosely anchor the adventitia of the ureter to the detrusor wall of the bladder at the site of ureteral entry (see Fig. 132.22F).

The cystotomy is subsequently closed in a two-layer fashion with 2-0 polyglactin suture (see Fig. 132.22G, H).

Boari Flap.

The Boari flap is first outlined and should be oriented obliquely downward across the anterior bladder wall such that the base is ipsilateral to the side of ureteral pathology (Fig. 132.23A). The base of the flap should measure at least 4 cm in width, with longer flaps requiring a wider base to ensure adequate blood supply. The apex of the flap should measure at least 3 cm in width. The length of the flap should approximate the size of the ureteral defect, although longer flaps (usually an additional 3 cm in length) may be used if ureteral tunneling is planned for a nonrefluxing anastomosis. It is critical that the ratio of length to-base width does not exceed 3 : 1 as this risks ischemia to the flap. Flap measurements should be taken with the bladder nondistended.

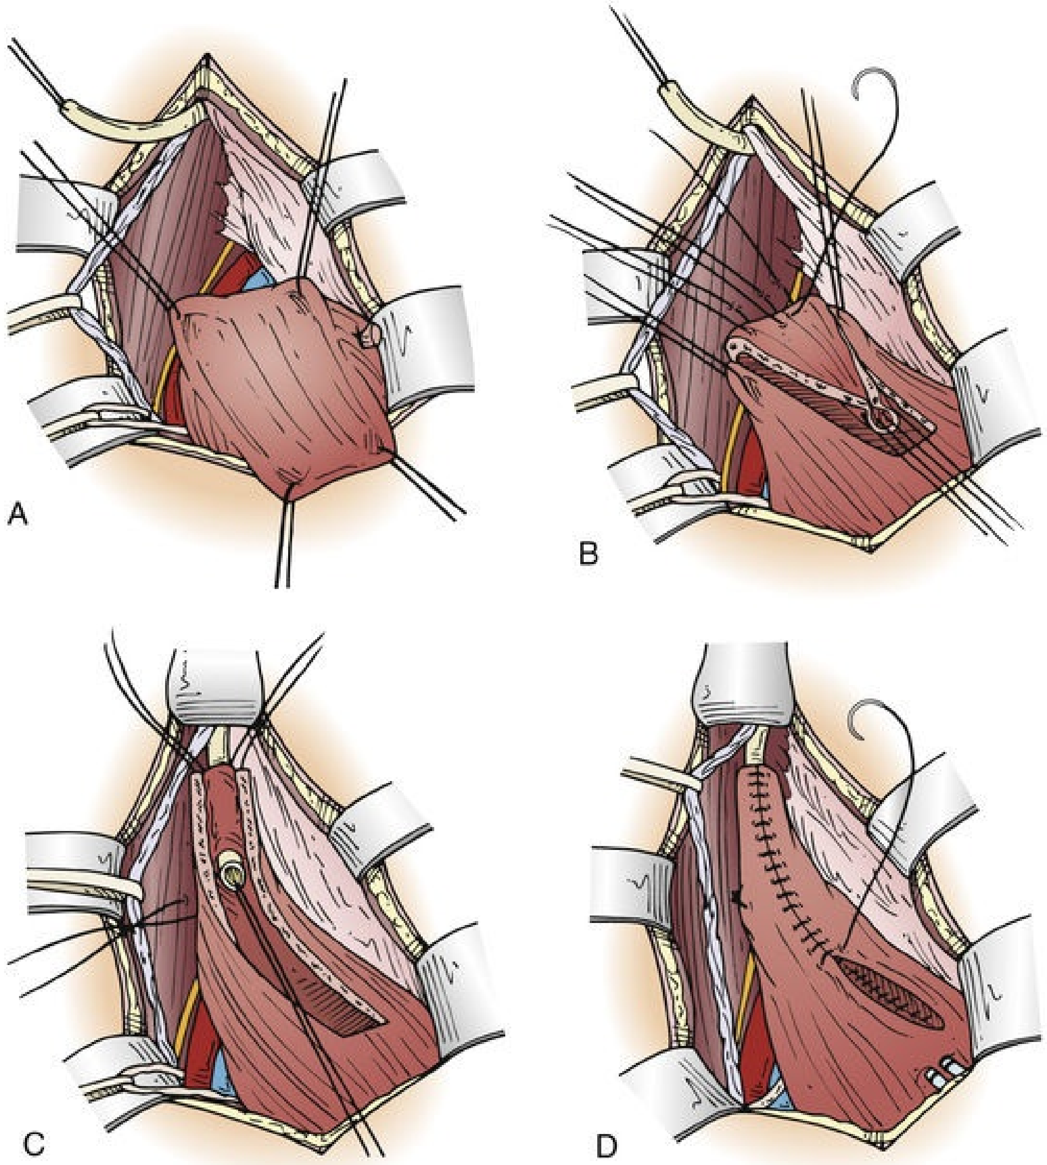

FIG. 132.23 Creation of a Boari flap. (A) An obliquely oriented flap is outlined spanning across the dome of the bladder. (B) After transmural incision along the outline of the flap, the flap is raised and the back wall of its base is sutured to the psoas minor tendon. (C) The ureter is tunneled through the Boari flap and anastomosed to the neo-orifice. (D) After placement of a ureteral stent, the bladder is closed in two layers. (Modified from Stein R, Rubenwolf P, Ziesel C, et al. Psoas hitch and Boari flap ureteroneocystostomy. *BJU Int* 112[1]:137–155, 2013.)

Electrocautery is used to incise along the planned outline of the flap, after which the flap is raised up to the ureter. The base of the flap is anchored to the psoas muscle tendon in a manner similar to that described for the psoas hitch (see Fig. 132.23B). Combining the Boari flap with a psoas hitch will reduce the size of the flap required to bridge the ureteral defect and thus help preserve bladder capacity.

In cases in which a nonrefluxing anastomosis is planned, there should be approximately 3 cm of overlap between the flap and the ureter to be reimplanted. A submucosal tunnel approximating 3 cm in length is generated via either an extravesical or intravesical approach as described earlier, with the ureter being delivered into the bladder through the posterior wall of the bladder flap just below its apex (see Fig. 132.23C). After completion of the ureterovesical anastomosis, the Boari flap is tubularized and closed with 2-0 polyglactin suture in a two-layer fashion (see Fig. 132.23D). 4-0 polyglactin sutures are placed extravesically to loosely anchor the adventitia of the ureter to the posterior wall of the bladder flap at its site of entry.

When the ureter is reimplanted in a refluxing manner, the spatulated end of ureter is anastomosed directly to the mucosal edges of the tubularized flap with 4-0 poliglecaprone suture. To avoid anastomotic stenosis, the width of the flap apex should be approximately three times the diameter of the ureter.

The cystotomy is subsequently closed in a two-layer fashion with 2-0 polyglactin suture.

In cases in which the Boari flap fails to adequately bridge the ureteral gap, the kidney may be mobilized and displaced downward.

Laparoscopic and Robotic Technique

Psoas Hitch.

Trocar placement for laparoscopic psoas hitch or advancement flap is similar to that for ureteral reimplantation and is depicted in Fig. 132.20. Trocar placement for the robotic approach is identical to that used for diverticulectomy, as seen in Fig. 132.10A. A transperitoneal approach is preferred.

The procedure begins by incising the ipsilateral white line of Toldt and identifying the ureter as it crosses the iliac vessels. The ureter is mobilized distally (Fig. 132.24A), and the diseased segment is excised, ensuring that the distal margin is well vascularized and healthy. In the case of stricture disease, a margin of the transected ureter is sent for frozen-section analysis to rule out malignancy. As described for primary ureteral reimplantation, a metal clip may be placed on the end of the transected ureter to permit passive dilation (see Fig. 132.24B). The bladder is filled with 200 mL of normal saline and mobilized by incising the peritoneum lateral to the obliterated umbilical ligaments bilaterally and transecting the urachus. Blunt dissection allows the bladder to “drop” posteriorly, and the space of Retzius is entered.

A clip on the end of the proximal transected ureteral segment may also be placed. (C) The ipsilateral bladder dome is displaced cephalad and sutured to the psoas minor tendon. (D) The ureter is spatulated and anastomosed to a cystotomy created in the ipsilateral posterior dome. (E) Before completion of anastomosis, a ureteral stent is placed in a retrograde fashion. (F) A pelvic drain is placed into the retropubic space. (Modified from Pugh J, Farkas A, Su LM. Robotic distal ureterectomy with psoas hitch and ureteroneocystostomy: Surgical technique and outcomes. *Asian J Urol* 2[2]:123–127, 2015.)

With the bladder mobilized, the posterior wall of the bladder is sutured to the psoas minor tendon with 2-0 polyglactin sutures to take any tension off the ureteral reimplantation (see Fig. 132.24C). This tendon may be identified superior and lateral to the ipsilateral common iliac vessels. Generally, division of the contralateral vascular pedicle to the bladder is not required, however, if further mobilization of the bladder is necessary, the superior and middle vesical arteries on the contralateral side can be ligated with and Endo GIA stapler. In a manner similar to open techniques, sutures should be placed through the psoas minor tendon superficially and oriented parallel to the direction of the muscle fibers so as to avoid entrapment of the genitofemoral nerve and deeper femoral nerve. Sutures in the posterior bladder wall should capture the detrusor muscle.

The ureter is reimplanted on the superior-lateral aspect of the displaced bladder dome segment in a refluxing, extravesical fashion as described earlier (see Fig. 132.24D,E). Placement of the ureter in this location allows for it to follow its native trajectory and be positioned on a relatively immobile portion of the bladder, reducing the likelihood for kinking.

The bladder is filled to 300 mL to identify any sites of anastomotic leakage, and a pelvic drain is placed through the 5-mm trocar site (see Fig. 132.24F).

Boari Flap.

The laparoscopic Boari flap was first described in humans by Fugita and Kavoussi (2001) in a series of three patients with distal ureteral obstruction (Fig. 132.25). The robotic-assisted laparoscopic approach was first reported several years later (Schimpf and Wagner, 2008). Trocar placement for laparoscopic Boari flap or advancement flap is similar to that for ureteral reimplantation and depicted in Fig. 132.20. Trocar placement for the robotic approach is identical to that used for diverticulectomy, as seen in Fig. 132.10A.

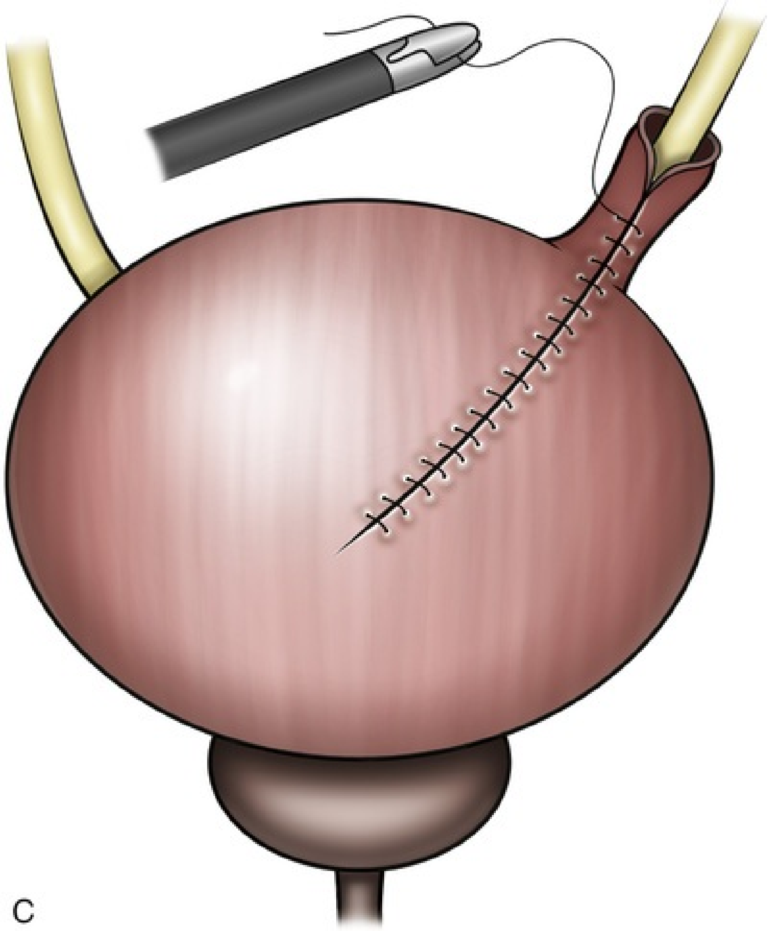

FIG. 132.25 Laparoscopic Boari flap. (A) An anterior flap is created beginning 2 cm from the bladder neck and extending to the bladder dome. (B) The spatulated ureter is anastomosed to the apex of the flap with interrupted 4-0 absorbable suture. (C) The flap is closed in a running fashion. (Modified from Fugita OE, Kavoussi L. Laparoscopic ureteral reimplantation for ureteral lesion secondary to transvaginal ultrasonography for oocyte retrieval. *Urology* 58[2]:281, 2001.)

As alluded to earlier, ligation of the contralateral bladder pedicle with an Endo GIA stapler and psoas hitch using 2-0 polyglactin suture often can provide enough mobilization to perform a ureteroneocystostomy (Modi et al, 2005; Schimpf and Wagner, 2008). If this maneuver does not suffice, a Boari flap or bladder advancement flap is performed.

Using electrosurgical scissors or a 10-mm LigaSure device, an anterior bladder flap is created beginning approximately 2 cm from the bladder neck and extending to the ipsilateral bladder dome; the apex of the flap is approximately 3 cm, and the base of the flap is approximately 4 cm (Fig. 132.26C) (Fugita and Kavoussi, 2001). Care should be taken to confirm that the base of the flap is wide enough to ensure adequate vascularity. The Boari flap is raised cephalad (see Fig. 132.26D), and its base is sutured to the psoas tendon (or muscle) (see Fig. 132.26E,F).

spatulated. (C) After the bladder is mobilized, the bladder is distended with methylene blue. A transmural incision is made along the outline of the Boari flap *(BF)* made across the bladder dome *(Bl).* (D) The boari flap *(BF)* is raised cephalad and approximated to the transected ureter to ensure a tension-free anastomosis. (E) Suture is placed through the detrusor layer at the base of the flap *(BF)* on the extravesical surface. (F) Suture is placed through the psoas muscle *(Ps)* to hitch the bladder flap to the psoas muscle. (G) The ureter *(U)* is anastomosed to the apex of the flap *(BF)* in a refluxing manner. (H) The cystotomy *(Bl)* is closed and the flap *(BF)* is tubularized after a stent is placed across the anastomosis. (Procedure performed by Alejandro R. Rodriquez, MD. Chief of Urology, Director of Robotic and Minimally Invasive Surgery, Samaritan Medical Center. Watertown, NY.)

The distal end of transected ureter is then spatulated (see Fig. 132.26B) and anastomosed to the apex of the flap with interrupted 4-0 absorbable suture (see Fig. 132.26G). After placement of a 7-Fr double-pigtail catheter over a guidewire, the flap is closed in a running fashion in two layers with 2-0 polyglactin suture or with the assistance of an Endo Stitch device (see Fig. 132.26H). The bladder is filled to 300 mL to identify any sites of anastomotic leakage, and a pelvic drain is placed through the 5-mm trocar site.

Advancement Flap.

The laparoscopic bladder advancement flap was first described by Lima et al. (2005) as a simplified alternative to a Boari flap. The bladder is opened with a transverse incision, placed one-third of the distance from the dome to the bladder neck (Fig. 132.27). The spatulated ureter is anastomosed to the bladder flap in a fashion similar to a Boari flap, described earlier. Because of its simplicity and versatility and the ability to gain considerable length that is on par with the Boari flap, it is the authors’ opinion that advancement flaps be utilized in lieu of the Boari flap to bridge longer ureteral defects not amenable to primary ureteroneocystostomy or psoas hitch (Fig. 132.28).

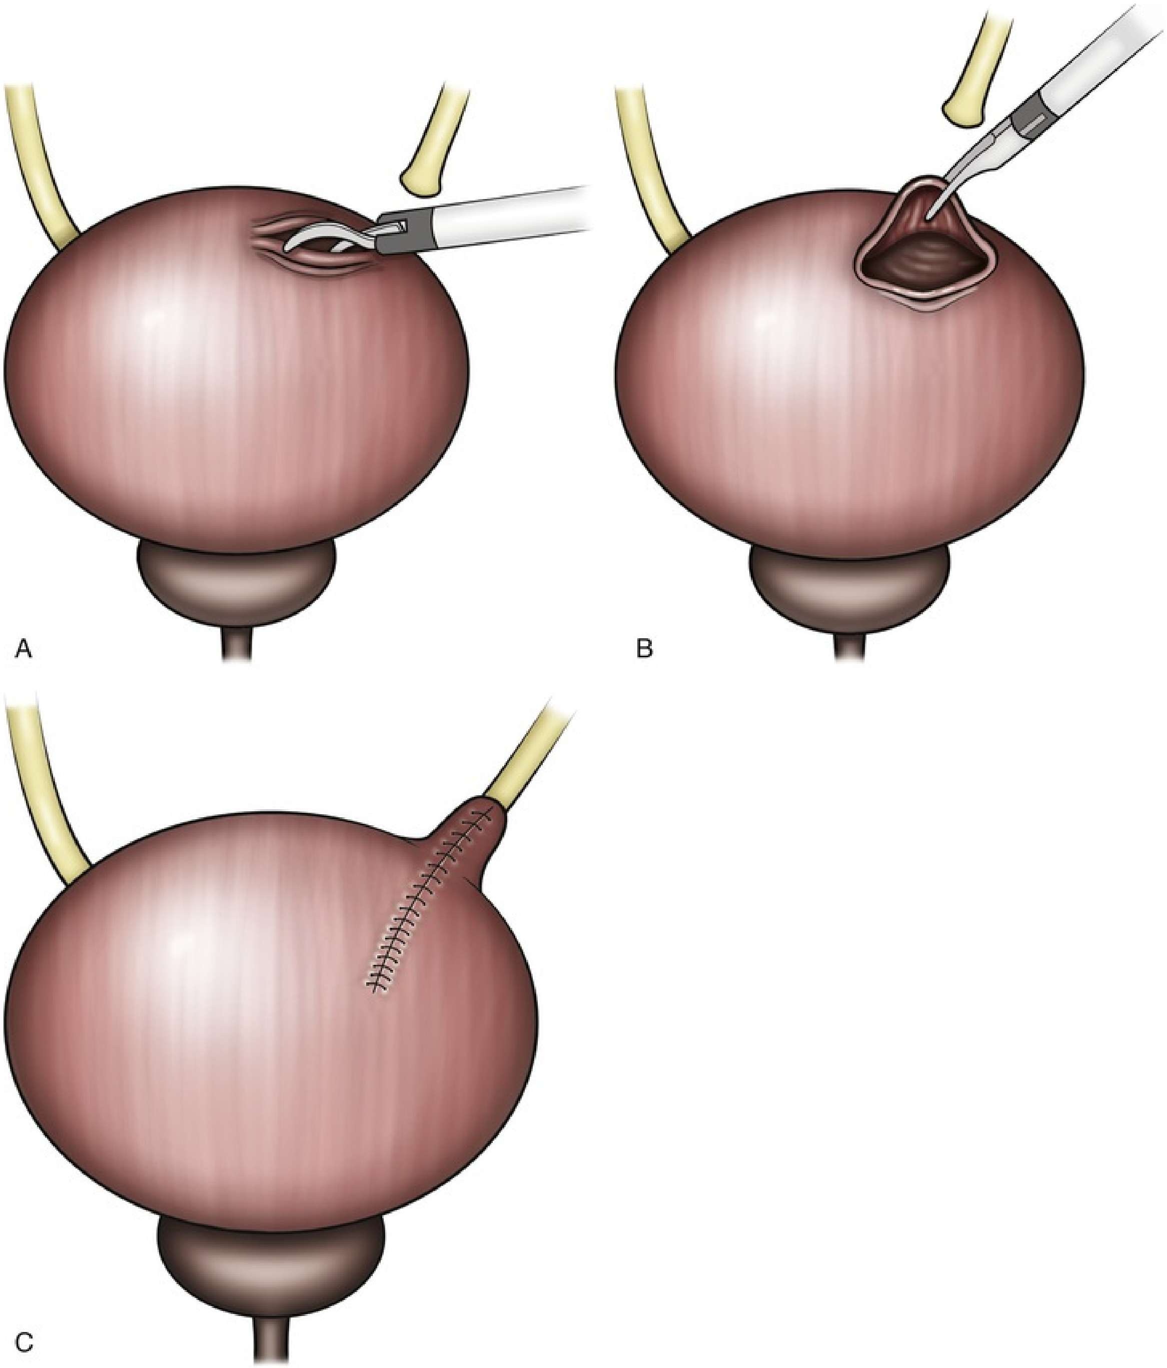

FIG. 132.27 Laparoscopic bladder advancement flap. (A) After spatulation of the ureter, a transverse opening is made on the anterior surface of the bladder one-third from the bladder dome. (B) As the incision is widened, the advancement flap is extended to the ureter. (C) The ureter is anastomosed to the advancement flap. (Modified from Lima GC, Rais-Bahrami S, Link RE, Kavoussi LR. Laparoscopic ureteral reimplantation: a simplified dome advancement technique. *Urology* 66[6]:1307, 2005.)

Laparoendoscopic Single-Site (LESS) Surgery Boari Flap.

The LESS Boari flap has been described and may improve cosmetic results. Either a homemade or a manufactured multichannel LESS port is used. Alternatively, multiple standard trocars can be introduced through a single site, typically the umbilicus. A robotic-assisted LESS approach also can be used. After access is obtained, the procedure is performed identically to laparoscopic and robotic flap creation (Khoder et al., 2011).

Postoperative Care and Complications

Postoperative management follows the same course as for ureteroneocystotomy described earlier. The nature of complications following the psoas hitch procedure and Boari flap creation are also similar to those described earlier for primary ureteral reimplantation.

Additional considerations include the potential for neuropraxy resulting from injury to the genitofemoral nerve or femoral nerve during bladder fixation to the psoas minor tendon. This can be averted by placing sutures superficially through the tendon in the direction of the muscle fibers. Injury to the iliac vessels may also occur as the bladder is displaced cephalad over the bifurcation of the common iliac artery. In the case of Boari flap creation, anastomotic stricture caused by ischemia may occur in the setting of a flap, which has a narrow base relative to its length; risk for ischemia can be minimized by obeying the 3 : 1 ratio between flap length and flap base width.

An overall reduction in bladder capacity may also result after creation of a Boari flap, which may lead to irritative voiding symptoms including urgency, frequency, and incontinence.

Outcomes

Since its first description in the mid-20th century, the open approach to the psoas hitch procedure has been widely utilized to gain up to 5 cm of additional length during distal ureteral reconstruction (Ehrlich et al., 1978; Warwick and Worth, 1969; Zimmerman et al., 1960). Among the largest of open series describing long-term outcomes after open psoas hitch reconstruction is that provided by Mathews and Marshal (1997), in which 20 patients who underwent psoas hitch ureteral reimplantation had follow-up data for a mean of 6 years after surgery. The majority of cases were performed for distal ureteral injury sustained during surgery. Surgical success, defined by the lack of need for further intervention, resolution of symptoms, and presence of normal or stable renal function, was noted in 17 patients, with one patient having continued flank pain despite a negative urologic workup (Mathews and Marshall, 1997). A separate single-institutional series of 24 open psoas hitch procedures performed for distal ureteral obstruction, the majority of cases resulting from operative injury, also revealed high success rates at a mean 33-month follow-up (Ahn and Loughlin, 2001). No patients had persistence of severe hydronephrosis or experienced deterioration in renal function, flank pain, or recurrent pyelonephritis after surgery. Additionally, the authors noted no difference in outcomes between immediate versus delayed repair (Ahn and Loughlin, 2001).

The use of a Boari flap has been shown to bridge longer ureteral defects, including those approaching 15 cm in length, while averting the need for more complex, higher-risk procedures such as ileal interposition or auto-transplantation (Benson et al., 1990). Motiwala et al. (1990) presented their initial experience with Boari flap ureteral substitution in 12 patients with ureteric injury sustained primarily during gynecologic procedures. The authors observed 1 major postoperative complication, although all patients had resolution of their obstruction on follow-up. A high success rate with low perioperative morbidity was also reported by Wenske et al. (2013) in a more contemporary series of 18 Boari flap ureteral reimplantations.

The ability to reproduce open techniques for psoas hitch ureteral reimplantation using laparoscopy has been also demonstrated by several authors (Ghosh et al., 2016; Gozen et al., 2010; Riedmiller et al., 1984). Nezhat et al. (2004) reported on their experience with six women who had undergoing laparoscopic psoas hitch ureteral reimplantation for distal ureteral pathology in the setting on infiltrative endometriosis. In this series, no patients experienced an intraoperative or 30-day postoperative complication. Additionally, imaging studies revealed no evidence of obstruction at 1-year follow-up in all patients. A similar series by Puntambekar et al. (2006) in five women undergoing laparoscopic psoas hitch ureteral reimplantation for injury sustained during gynecologic procedures reported favorable perioperative outcomes including a mean surgical time of 220 minutes, mean estimated blood loss of 150 mL, and an average hospital length of stay of 3 days. No complications were observed, and follow-up urography demonstrated resolution of obstruction with no evidence of reflux on cystogram. The authors did, however, stress the importance of a proper intracorporeal suturing technique to facilitate surgical success. More contemporary series on laparoscopic distal ureteral reconstruction routinely consider patients undergoing primary ureteroneocystotomy in aggregate with those undergoing psoas hitch reimplantation, indicating its more widespread integration into the minimally invasive treatment armamentarium for distal ureteral defects (Gozen et al., 2010; Pompeo et al., 2013; Rassweiler et al., 2007).

In a similar regard, laparoscopic techniques for Boari flap creation are being utilized for ureteral reconstruction in the setting of longer-segment ureteral defects (Ghosh et al., 2016; Gozen et al., 2010). The first clinical series of laparoscopic ureteral reimplantation with a Boari flap was reported in 2001 and involved three patients (Fugita and Kavoussi, 2001). The approach was demonstrated to be feasible with a mean operative time of 220 minutes and estimated blood loss ranging from 400 to 600 mL. With a mean follow-up period of 11 months, all patients had resolution of obstruction. Castillo et al. (2005) reported a slightly larger series of laparoscopic Boari flap in eight patients. Operative times (mean 157 minutes), blood loss (mean 124 mL), and hospital stay (mean 3 days) further validated the feasibility of the technique. Two complications occurred, including one pulmonary embolism and one episode of urinary leakage at the anastomosis requiring laparoscopic repair. With a mean follow-up of 18 months, all patients had resolution of obstruction (Castillo et al., 2005).

Seideman et al. (2009) reported the largest single-center series of laparoscopic Boari flap in 21 of 45 patients undergoing laparoscopic ureteral reimplantation with significant follow-up (mean 24 months). Median length of stay was 3 days, and median estimated blood loss was 150 mL. Complications included small bowel obstruction in one patient, *Clostridium difficile* colitis and respiratory distress in one patient, and urinary leakage in two patients that was managed conservatively in both cases. In a multi-institutional series of 30 patients undergoing a laparoscopic Boari flap procedure, excellent outcomes were achieved (Castillo et al., 2013). In this series, mean operative time was 161 minutes, and mean estimated blood loss was 123 mL with no intraoperative complications or conversion to open surgery. Postoperative complications occurred in 17% of patients, with a success rate of 97% at a mean follow-up of 32 months (Castillo et al., 2013).

Increased utilization of the robotic platform for urologic surgery has generated considerable interest in its use for more complex reconstructive procedures involving longer defects of the distal and mid-ureter (Allaparthi et al., 2010; Musch et al., 2013; Schimpf and Wagner, 2008, 2009). A multi-institutional review of 12 cases of robotic ureteral reimplantation with psoas hitch performed by three experienced robotic surgeons for benign indications demonstrated high efficacy of the procedure with a mean operating time of 173 minutes, mean blood loss of 48 mL, and hospital stay of 4.3 days (Patil et al., 2008). Additionally, no intraoperative or postoperative complications were encountered with all procedures having been completed robotically. All patients were asymptomatic after a mean follow-up of 15.5 months, with imaging demonstrating no hydronephrosis in 10 patients and only mild residual hydronephrosis in two patients (Patil et al., 2008).

In a subsequent series of 16 patients undergoing robotic-assisted reconstruction of the distal ureter, Musch et al. (2013) reported on outcomes associated with seven cases in which psoas hitch was performed and four cases for which a Boari flap was also created. Open surgery was required in one case because of massive peritoneal adhesions from a previous pancreatectomy, and two patients experienced a major postoperative complication, characterized by prolonged urinary leak in one case and bladder insufficiency with urinary leak in the second. At a medium follow-up of 10.2 months, however, 94% of patients remained without evidence of urinary tract obstruction, and 81% were free of any clinical symptomatology (Musch et al., 2013). A similar investigation of robotic Boari flap ureteral reimplantation performed in eight patients for benign ureteral stricture disease revealed similar efficacy, with a mean operative time of 171.9 minutes, blood loss of 161.3 mL, and no intraoperative complications or occurrences of open conversion (Do et al., 2014). One postoperative anastomotic leak was observed, which resolved with conservative management.

Thus, although the majority of laparoscopic and robotic series to date are small in study size, they indicate that, in experienced hands, excellent results can be achieved with minimally invasive techniques.

Enterocystoplasty

Description

Bladder augmentation in adults is most frequently indicated in the setting of neurogenic bladder (either congenital or acquired) when more conservative attempts at improving bladder compliance are unsuccessful (Wiener et al., 2011). Less often, augmentation cystoplasty is performed after partial cystectomy when resection has led to a significant reduction in bladder capacity. The intrinsic distensibility of bowel makes its use ideal for reducing intravesical pressures and improving reservoir function of the bladder, although it is critical that the isolated segment is adequately detubularized to subvert coordinated peristaltic contractions that may mitigate this purpose.

Traditionally performed via an open approach, there has been a gradual evolution in the use of minimally invasive techniques for enterocystoplasty (Docimo et al., 1995; Gill et al., 2000). Over the past decade, ileocystoplasty has emerged as the most widely employed technique. Reports of laparoscopic, robotic, and LESS bladder augmentation have documented the reproducibility of these techniques by purely intracorporeal and partly extracorporeal approaches.

Evaluation and Surgical Indication

Among patients with known neurogenic dysfunction of the bladder, there has been considerable evolution in noninvasive management strategies that have made the need for enteroplasty a more advanced option. Indeed, continuous intermittent catheterization, anticholinergics, intravesical injections with botulinum toxin, and sacral neuromodulation form the mainstay of therapy in these patients (Apostolidis et al., 2009; Cardenas et al., 2011; Jamison et al., 2013; Sadiq and Brucker, 2015). However, in situations in which noncompliance of the bladder persists despite these measures, augmentation cystoplasty with bowel should be considered, particularly if there is evidence of upper tract deterioration, hydronephrosis, or significant incontinence (Utomo et al., 2014).

Urodynamics is an important tool in this patient population as measurement of detrusor leak point pressure is a strong indicator of the elastic properties of the bladder and risk for renal deterioration. Video-urodynamics is often preferred as this allows for simultaneous evaluation of bladder contour, the presence of associated anomalies (e.g., diverticula), and presence of vesicoureteral reflux. Ultrasonography should also be routinely performed as the development of hydronephrosis or parenchymal atrophy indicates poor bladder wall compliance.

Symptoms of frequency, urgency, nocturia, or incontinence in patients who have previously undergone partial cystectomy may indicate a significant reduction in bladder capacity. Conservative measures, similar to those for neurogenic bladder dysfunction, should be implemented initially, with enterocystoplasty reserved only for cases of refractory symptomatology. Ideally, preoperative screening will have selected against those patients at risk for clinically significant reduction in bladder capacity. Urodynamics may be utilized in these patients to better characterize bladder function and response to noninvasive interventions.

Resection of the intestine and subsequent integration into the urinary tract carries the potential for metabolic derangement. As such, a full serum chemistry is necessary before surgical planning. In particular, with ileum being most often utilized for bladder augmentation, careful screening for Vitamin B_{12} and fat-soluble vitamin deficiency is necessary. Additionally, perturbations in acid balance resulting from the interaction of urine with intestinal mucosa warrants careful consideration, particularly in patients with renal failure caused by compromised ability to regulate serum pH. As ileum is most widely utilized for purposes of bladder augmentation, primary concern relates to the development of a chronic metabolic acidosis state in these individuals and associated risk for bone demineralization.

Technical considerations when determining candidacy for augmentation enterocystoplasty include a careful understanding of the patient's medical history. Presence of Crohn's disease or previous intestinal surgery may place patients at risk for short gut syndrome after further bowel resection. Prior radiation exposure to the bowel may preclude ability to isolate an intestinal segment with a durable blood supply. The need for continuous intermittent catheterization will remain in the majority of cases where augmentation cystoplasty is performed, thus manual dexterity and anatomic feasibility to catheterize must be confirmed before treatment, especially when being performed for neurogenic dysfunction.

The need for concomitant interventions should also be factored into surgical planning. Patients with neurogenic dysfunction with stress urinary incontinence may undergo simultaneous placement of a sling or artificial sphincter. In individuals undergoing creation of a continent catheterizable stoma, bladder neck closure may be planned, particularly in the context of incontinence. Nonrefluxing ureteral reimplantation for high-grade reflux may be planned in cases of renal dysfunction and concern for relative persistence of high intravesical pressures despite augmentation cystoplasty.

Nearly any portion of the gastrointestinal system can be utilized for purposes of bladder augmentation. However, the ileum is most often utilized given its abundance, ease of mobilization resulting from the intraperitoneal location and long mesentery, and rich vascular supply. If a continent catheterizable channel is desired, particularly in cases in which the bladder neck has been closed, an ileocecal segment may be used. Sigmoid colon is attractive in patients with neurogenic dysfunction as there is often redundancy of the mesentery, which facilitates mobilization. Patients in whom colon is being used for augmentation should receive colonoscopy to ensure no malignancy is present.

Presented here are techniques for performing open, laparoscopic, and robotic ileocystoplasty. The general principles demonstrated here apply when harvesting other intestinal segments.

Surgical Technique

Open Technique

The patient is placed supine on the operating table with the table flexed at the anterior superior iliac spine. When using ileal or colonic segments of bowel, the patient is prepped from the thigh to just above the umbilicus; the incision may need to be carried more cephalad if a gastric segment is utilized.

A midline skin incision is made from the umbilicus to the pubic symphysis and carried down through the subcutaneous tissue to the level of the rectus fascia. The fascia is incised in the midline the length of the incision, exposing the underlying rectus muscle. The bellies of the muscle are split at the midline linea alba, and the transversalis fascia is incised. The peritoneum is entered sharply and incised the length of the incision.

The space of Retzius is developed with blunt dissection. Extensive dissection of the lateral pelvic gutters is not necessary as transposition of the isolated bowel segment generally occurs onto the most cephalad portion of the bladder.

A 25-cm length of ileum is isolated approximately 20 cm proximal to the ileocecal valve to reduce malabsorption risk related to resection of the terminal ileum (Fig. 132.29A). The candidate segment of ileum is brought down into the pelvis and approximated onto the dome of the bladder to ensure feasibility for a tension-free anastomosis.

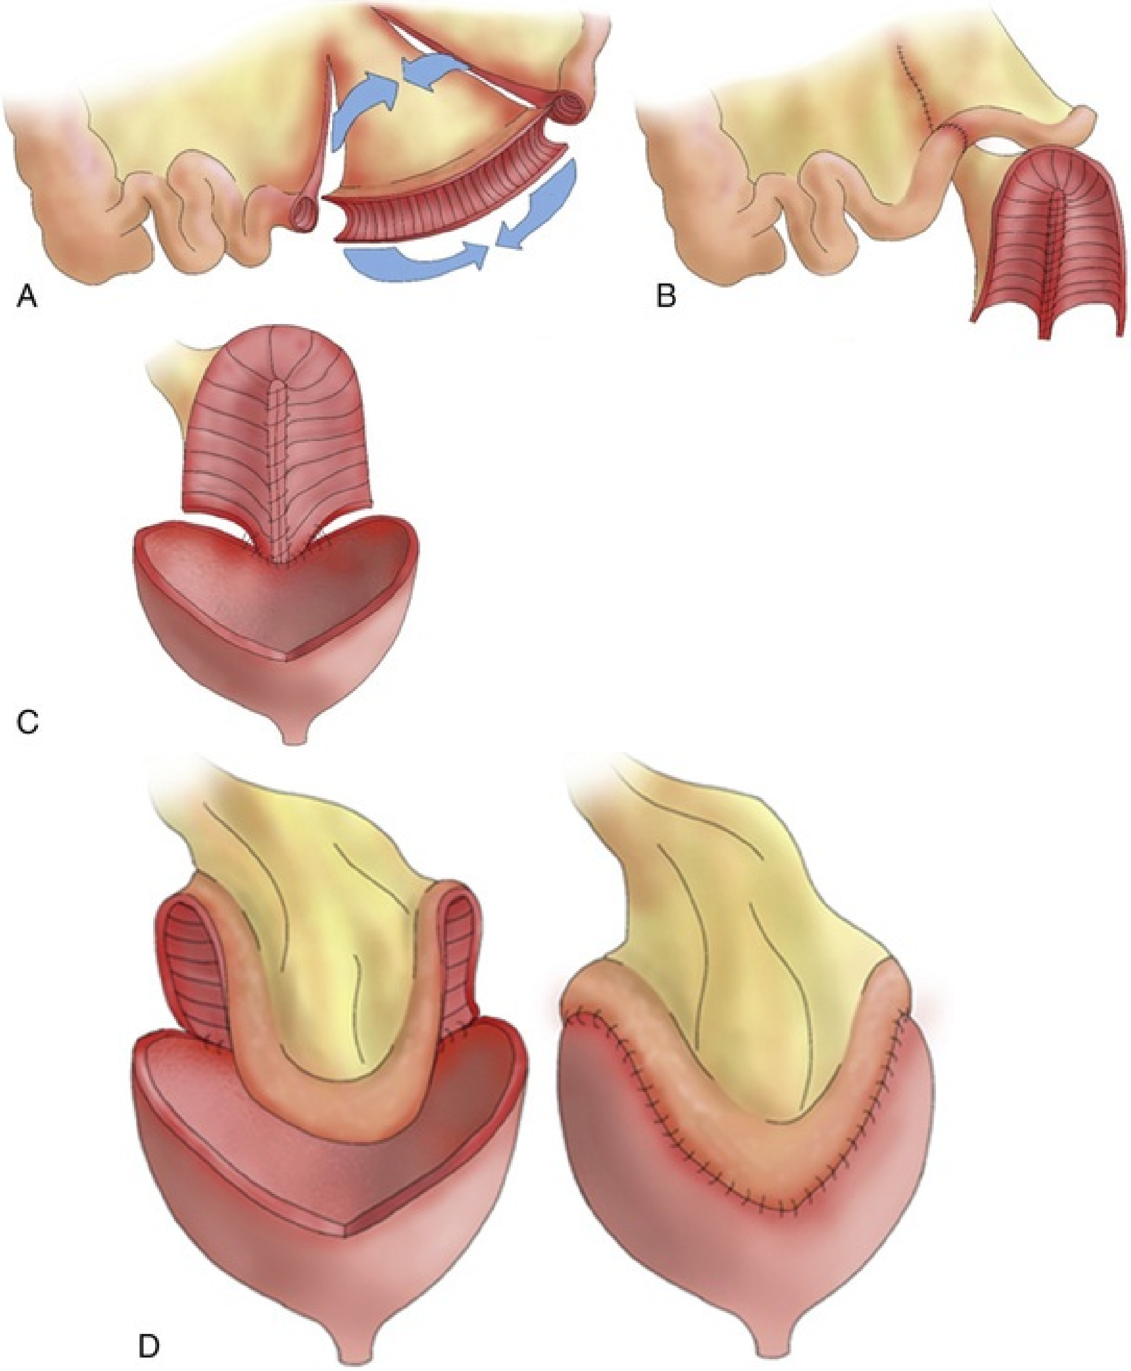

FIG. 132.29 Open enterocystoplasty. (A) A 25-cm segment of ileum is isolated after which is it detubularized along its antimesenteric surface. (B) The bowel segment is folding into a U-shape to form an intestinal flap. (C) The bladder is bivalved by incision along the midline dome. (D) The U-shaped intestinal flap is anastomosed to the bladder dome allowing for a

wide-mouth anastomosis. (Modified from Breen M, Phelps A, Estrada C, Chow JS. The role of imaging in pediatric bladder augmentation. *Pediatr Radiol* 45[10]:1440–1447, 2015.)

Before harvesting the intestinal segment, the mesentery is transilluminated to visualize the vascular supply and ensure isolation of a bowel segment with an adequate arterial arcade, extending ideally to the edges of the segment. 2-0 silk stay sutures are loosely placed on the antimesenteric surface of the intestine to demarcate the boundaries of resection. A small mesenteric window is made along the mesenteric surface of the intestine at the marked boundaries of resection. An Endo GIA stapler is inserted through this window and used to divide the intestinal segment to be used for bladder augmentation. The mesentery is divided toward its root with a 10-mm LigaSure device or Endo GIA stapler (see Fig. 132.29A). Care should be taken to avoid blood vessels during division of the mesentery. Additionally, the mesenteric base of the isolated intestinal segment should be kept broad to minimize the risk for torsion of the pedicle.

Continuity of the intestinal segments is reestablished via a side-to-side anastomosis using an Endo GIA stapler. Allis clamps are used to appose the edges of the intestinal wall defect at the elbow of the anastomosis under which a TA stapler (Covidien, Mansfield, MA) is used to complete the anastomosis staple line. The mesenteric defect is closed with 2-0 polyglactin sutures placed longitudinally through the mesentery to avert internal herniation. The intestine with the closed mesenteric trap should be situated on top of the isolated segment of bowel that is to be used for bladder augmentation.

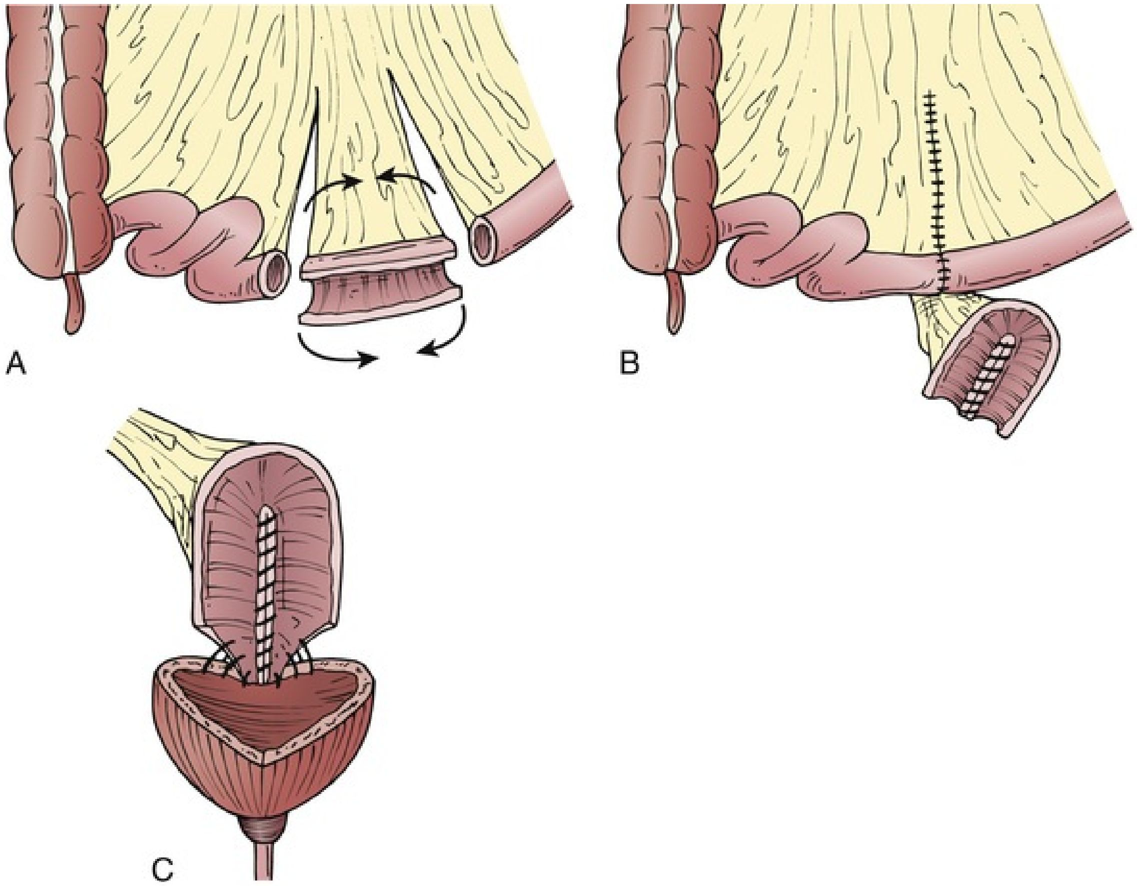
The staple lines are resected off the ends of isolated intestinal segments, and the segment is copiously irrigated. The segment is then detubularized by incising its antimesenteric surface transmurally with electrocautery (see Fig. 132.29A). The detubularized intestinal patch is subsequently configured into a U-arrangement, and the sides are sutured with full-thickness 2-0 polyglactin suture in a running fashion (see Fig. 132.29B).

A longitudinal incision is made along the dome of the bladder from anterior to posterior, essentially bivalving the bladder. The bladder wall defect should be patent enough to facilitate a wide-mouth anastomosis as this will allow the intestinal patch to better assume the reservoir function of the bladder (see Fig. 132.29C). The U-shaped detubularized intestinal patch is sutured to the edges of the bladder dome defect circumferentially, ensuring that transmural sutures are placed through the intestinal segment and bladder wall (see Fig. 132.29D).

Before completion of the vesiointestinal anastomosis, a suprapubic tube should be placed through a separate cystotomy and brought out through the skin. Additionally, if the bladder neck is open, a large-bore Foley catheter should be placed under visualization. The integrity of the anastomosis is assessed by irrigating the bladder through the Foley catheter and/or suprapubic tube. Any sites of leakage should be reinforced with figure-of-eight 2-0 polyglactin suture. A pelvic drain is placed in the retropubic space and secured to the skin. The fascia and skin are closed in the standard fashion.

Laparoscopic and Robotic Techniques

The procedure begins with cystoscopic evaluation and placement of bilateral open-ended or single-J ureteral catheters, which are secured to a urethral catheter. Pneumoperitoneum is established. Laparoscopic or robotic enterocystoplasty is performed using three to five trocars depending on the surgeon's experience and preference (Fig. 132.30A).



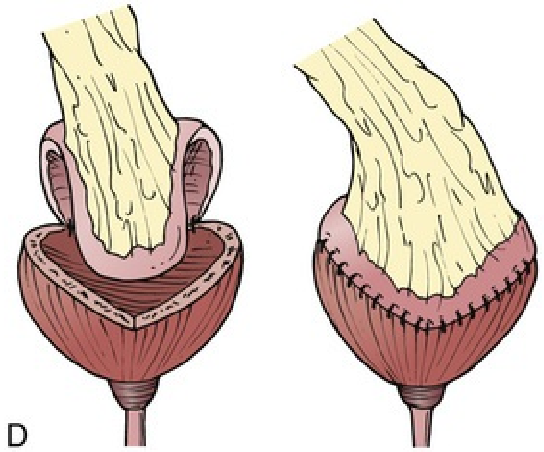


FIG. 132.30 Technique for minimally invasive enterocystoplasty. (A) Four-port transperitoneal technique is employed including an umbilical port, one port at each lateral border of the rectus muscle at the level of the umbilicus, and a port in the iliac fossa at the level of the anterior superior iliac spine. (B) The selected bowel segment (≈20 cm) is exteriorized through an extension of the umbilical port incision. Alternatively, the bowel work can be performed intracorporeally. The anteroposteriorly bivalved bladder is shown. (C) Ileoileal reanastomosis is performed cephalad (anterior) to the isolated bowel segment, which is detubularized and cleansed. Proper orientation of the bowel mesentery must be maintained. (D) Ileovesical anastomosis is performed in a circumferential manner with continuous, full-thickness, freehand laparoscopic suturing with 2-0 polyglactin suture on a CT-1 needle. The completed augmentation ileocystoplasty is shown in the inset. (Reprinted with permission from The Cleveland Clinic Foundation. From Gill IS, Rackley RR, Meraney AM, et al. Laparoscopic enterocystoplasty. *Urology* 55[2]:178–181, 2000.)

The bladder is fully mobilized by incising the peritoneum lateral to the obliterated umbilical ligament bilaterally, and the urachus is divided to “drop” the bladder posteriorly and enter the space of Retzius. An appropriate 15- to 20-cm segment of bowel is chosen taking care to ensure an adequate vascular pedicle and that the segment will reach to the bladder neck (see Fig. 132.30B). The bowel work can be completed via a purely laparoscopic approach (Meng et al., 2002) or extracorporeally by extending the length of the umbilical incision (Gill et al., 2000) as described later in this chapter.

In either approach, the segment is harvested using an Endo GIA stapler, and the mesentery can be divided with additional reloads of the Endo GIA stapler or with a 10-mm LigaSure device, as described earlier for the open technique. Bowel continuity is reestablished with a side-to-side anastomosis using the Endo GIA stapler. The anastomosis is completed using a TA stapler if performed extracorporeally and with a series of Lembert sutures if performed using intracorporeal suturing (see Fig. 132.30C). The mesenteric window, or “trap,” is closed to prevent internal herniation.

The bowel segment is irrigated copiously, the staple lines are excised on each end, and the segment is then opened along the antimesenteric border. The sides of the now detubularized ileal bowel segment are approximated to form a *U*-shaped segment with running 2-0 polyglactin suture, as described for the open technique. At this time, the bladder is filled with saline and bivalved at the midsagittal line. The segment is brought down to the pelvis without tension or torsion of the mesenteric pedicle (see Fig. 132.30D).

With the bowel segment oriented so that the apex of the *U* is positioned anteriorly at the bladder neck, the patch is sutured to the bladder in a running continuous fashion with 2-0 polyglactin suture, beginning posteriorly and ending anteriorly (see Fig. 132.30D) (Elliott et al., 2002; Gill et al., 2000; Meng et al., 2002). The integrity of the completed augmentation is confirmed by irrigating the bladder via the Foley catheter, and finally a pelvic drain is positioned through an established port.

Laparoscopic and robotic ileocecocystoplasty with creation of a catheterizable stoma also have been described (Gill et al., 2000; Gundeti et al., 2008). As an alternative to vesicoplasty for select patients, appendicovesicostomy has been performed laparoscopically (Hsu and Shortliffe, 2004; Lorenzo et al., 2007) and with robotic assistance (Lendvay et al., 2008). More recently, LESS enterocystoplasty has been reported, but larger series are needed to validate the efficacy and safety of the approach (Desai et al., 2009).

Postoperative Care and Complications

Postoperatively, a Foley catheter is kept to drainage for approximately 1 week with a cystogram performed before removal. The pelvic drain is removed typically after 48 hours once the output has decreased; a drain creatinine measurement is optional and should be interpreted in the context of the drain output.

Patients undergoing enterocystoplasty are subject to complications similar to bladder diverticulectomy. Urinary extravasation across the suture lines may result from inadequate suturing or ischemia of the intestinal flap; it is for this latter reason that a robust vascular arcade be preserved during flap harvest. Clinical presentation and management of urine leak are described earlier in the section for bladder diverticulectomy. Patients undergoing enterocystoplasty are also subject to urinary tract infection, bowel injury, and urinary fistula formation. Intraabdominal infectious complications in particular may occur during irrigation of the bowel segment and detubularization, particularly if proper isolation precautions are not used during this portion of the procedure.

Complications unique to enterocystoplasty include bladder perforation, stone formation, systemic metabolic derangements, and neoplasia (pertinent to cases in which colon segment is used). Continuous intermittent catheterization is imperative in patients undergoing augmentation cystoplasty as failure to do so risks perforation. Preoperative operative planning should account for the manual dexterity of patients as this will also influence type of augmentation performed; individuals with unfavorable body habitus who cannot catheterize at the bladder neck may be better served with a continent ileocecocystoplasty, whereas individuals unable to catheterize or who demonstrate poor compliance can undergo an incontinent ileovesicostomy. Bladder perforation should be suspected in cases of abdominal pain, fever, or acute abdominal distension and should prompt CT of the abdomen and pelvis; a high index of suspicion is required in the neurogenic population as sensory deficits may be present. Perforation is a surgical emergency and requires exploration.

Higher propensity for bladder stone formation is multifactorial and involves mucus production by the interposed intestinal segment, the higher burden of bacterial colonization and risk for infection, and urinary stasis (DeFoor et al., 2004). Irrigation is thought to reduce retention of mucus within the bladder, although the true benefit remains the subject of debate (Hensle et al., 2004). Symptomatic bacterial infections should be treated with antibiotics. Increased risk for cancer has been reported in augmented bladders, although the exact incidence is difficult to discern. Nevertheless, bladders augmented with bowel segments appear to be at risk for not only adenocarcinoma but also urothelial carcinoma (Austen and Kalble, 2004). Surveillance endoscopy is recommended after 10 years of initial surgery. Routine blood work is necessary to screen for metabolic derangements, including vitamin deficiencies.

Outcomes

Open augmentation cystoplasty is a widely utilized treatment option for patients with neurogenic dysfunction (Wiener et al., 2011). Given minimally invasive techniques have only recently emerged, long-term outcome studies are available primarily for procedures performed using open techniques (Gurung et al., 2012; Herschorn and Hewitt, 1998).

The earliest of reports detailing the efficacy of enterocystoplasty involving use of the cecum or ileum were provided by Linder et al. (1983), who described their outcomes at a mean 38-month follow-up for 18 patients treated for neurogenic dysfunction. The authors cited high success related to the procedure as 82% of patient remained continent at last follow-up (Linder et al., 1983). Longer-term follow-up was provided by Gurung et al. (2012) in 19 adult patients (mean age 28.9) undergoing ileocystoplasty for detrusor overactivity secondary to spinal cord injury. At a mean 14-year follow-up, the authors demonstrated significant improvement in bladder capacity and reduction in intravesical pressures using video-urodynamic testing. Additionally, the authors demonstrated a very high-level of patient satisfaction on quality-of-life questionnaire, with no reports of change in bowel or sexual function. Of note, over 50% of patients experienced a complication related to their augmentation procedure at some time point; the majority were related to the formation of bladder stones (Gurung et al., 2012).

These results echo the findings of a similar report by Quek and Ginsberg (2003) describing long-term outcomes in a cohort of patients undergoing enterocystoplasty for neurogenic bladder. In their series of 26 patients, a mean 8-year follow-up demonstrated resolution of incontinence in 96% of patients and a significant improvement in bladder capacity. Urodynamics studies performed in all patients revealed a reduction in mean maximum detrusor pressures of appropriately 61 cm H_2O. Additionally, patient satisfaction after the procedure was nearly 100%, with very few patients reporting bowel dysfunction. The authors did note, however, that efficacy of the procedures was observed in the context of a secondary procedure in almost 50% of patients at some time point after the initial surgery (Quek and Ginsberg, 2003).

These results indicate that open augmentation cystoplasty is an effective treatment strategy for patients with neurogenic dysfunction experiencing refractory voiding symptoms (e.g., incontinence, overactivity) or at risk for upper tract dysfunction secondary to high intravesical pressures. Although there is a relatively high risk for complications with long-term follow-up, the majority pose low morbidity and are manageable with secondary interventions.

The data on minimally invasive procedures are less robust, although small series do report feasibility and efficacy with intermediate follow-up (Gould and Stoffel, 2011). Docimo et al. performed the first pure laparoscopic gastrocystoplasty in a patient with a five-port technique (Docimo et al., 1995). The procedure involved almost 11 hours of operating time and a 13-day hospitalization. A laparoscopic-assisted approach, in which the laparoscopic work was largely limited to bowel mobilization, followed (Chung et al., 2004; Hedican et al., 1999). Gill et al. reported the first laparoscopic ileocystoplasty, sigmoidocystoplasty, and cecocoloplasty (Gill et al., 2000). Bowel harvest and anastomotic work was done extracorporeally with a four-port approach. In this series of three patients, operative times of 5 to 8 hours and blood loss of 50 to 200 mL were reported. A rectus sheath hematoma was the only complication that occurred.

The first purely laparoscopic ileocystoplasty in a human was reported in 2002 (Elliott et al., 2002; Meng et al., 2002). The patient underwent a 9-hour procedure and required a 13-day hospitalization secondary to prolonged ileus. A subsequent larger series of laparoscopic cystoplasty comprised six patients who underwent pure laparoscopic ileocystoplasty and an antegrade continence enema procedure (Shadpour et al., 2005). Operative times were 5 to 8.5 hours, with a median hospitalization of 5 days. Complications included one ileal anastomotic leak that resolved conservatively and one appendiceal stomal stenosis requiring revision. With intermediate-term follow-up (13 to 16 months), all patients were continent of urine between catheterizations, and nearly all had perfect fecal continence.

Purely intracorporeal robotic augmentation ileocystoplasty with and without Mitrofanoff appendicovesicostomy has also been described (Al-Othman et al., 2008; Gundeti et al., 2008). The technique is essentially identical to the laparoscopic approach, but it may facilitate the learning curve for intracorporeal suturing. In a recent series of five cases of robotic ileocystoplasty reported by Gould and Stoffel (2011), mean operative time was 6.4 hours, blood loss was 180 mL, and length of stay was 7 days. Only one patient experienced a postoperative complication involving formation of urinoma causing ileus; this resolved spontaneously with conservative management. At last follow-up, all patients were continent and had normal upper tract imaging (Gould and Stoffel, 2011). Flum et al. (2014) recently published a larger, more contemporary review of their experience performing robotic augmentation enterocystoplasty, in which the entirety of the procedure was performed intracorporeally. Of 22 patients treated, 15 underwent enterocystoplasty alone, whereas seven patients additionally received a continent catheterizable channel. Mean operative time was 365 minutes, and blood loss was only 110 mL. One conversion to open surgery was necessary, and four major complications were reported. At a mean follow-up of 38.9 months, mean cystometric capacity increased by 52% and mean maximal detrusor pressure decreased by 40 cm H_2O on urodynamic testing

(Flum et al., 2014).

These results indicate that continued experience with minimally invasive techniques for augmentation cystoplasty may be allowing for improvement in perioperative and postoperative outcomes.

Partial Cystectomy and Urachal Surgery

Description

Partial cystectomy is most frequently utilized for select patient populations with muscle-invasive urothelial carcinoma or urachal adenocarcinoma who are amenable to bladder preservation (Knoedler et al., 2012; Wadhwa et al., 2006). However, there are several benign indications for which partial cystectomy is performed as well.

The majority of benign bladder tumors can either be managed conservatively, with removal of the offending stimulus, or using transurethral resection. However, certain tumors that grow large in size, demonstrate a locally infiltrative growth pattern, or manifest with refractory local symptomatology may require surgical resection. The most common tumors exhibiting such properties are bladder leiomyomas and paragangliomas (Agarwal et al., 2002). Other benign processes for which partial cystectomy is indicated include bladder endometriosis, urachal anomalies, and colovesicular or vesicovaginal fistulas that have failed conservative management strategies.

Evaluation and Surgical Indications

Selection criteria when partial cystectomy is performed for benign indication are not as stringent as for cases of malignancy. Issues of tumor multiplicity, concomitant presence of premalignant lesions (e.g., CIS), and prior history of recurrence patterns are generally less relevant in these circumstances. The primary consideration is whether partial resection of the bladder wall would decrease bladder capacity to the point of compromising postoperative quality of life. As such, partial cystectomy should be avoided in patients with a small-volume bladder or who have severe dysfunctional voiding symptoms at baseline.

The presence of bladder malignancy must be ruled out as there are some important technical aspects to surgery that differ between benign and malignant disease processes (e.g., wide margins and lymph node dissection when performed for malignancy). In this regard, a workup that is similar to that for bladder malignancy is generally pursued in all individuals before surgery. This includes cross-sectional excretory-phase imaging, cytology, cystoscopy, and, in most cases, bladder biopsy to establish a histologic diagnosis. It is important to note tumor location as this may influence the feasibility of partial cystectomy, particularly for lesions located near the bladder base. If the lesion is situated near the ureteral orifice, simultaneous ureteral reimplantation may be necessary. Considerations specific to the type of pathology are described in the following section.

Leiomyoma

Leiomyomas of the bladder are rare smooth muscle tumors that have been reported primarily in women of childbearing age (Knoll et al., 1986). Histologically, they are similar in appearance to fibroids that occur most commonly in the uterus. The etiology is poorly understood given their rarity, however, hormonal imbalances or chronic detrusor irritation are speculated (Cornella et al., 1997). As these tumors may grow large in size, typical symptoms associated with their presence include urinary outlet or ureteral obstruction, irritative voiding symptoms, pelvic pain, and hematuria (Bazeed and Aboulenien, 1988; Belis et al., 1979). Morphologically, leiomyomas of the bladder can have a predominant endovesical, intramural, or extravesical pattern of growth (Fig. 132.31). As such, transvaginal ultrasonography and less often magnetic resonance imaging (MRI) can be used to characterize lesions (Illescas et al., 1986; Maya and Slywotzky, 1992). Whereas small-sized endovascular lesions may be amenable to transurethral resection, larger lesions or those with intramural composition may necessitate wide local resection to minimize the risk for tumor regrowth (Belis et al., 1979).

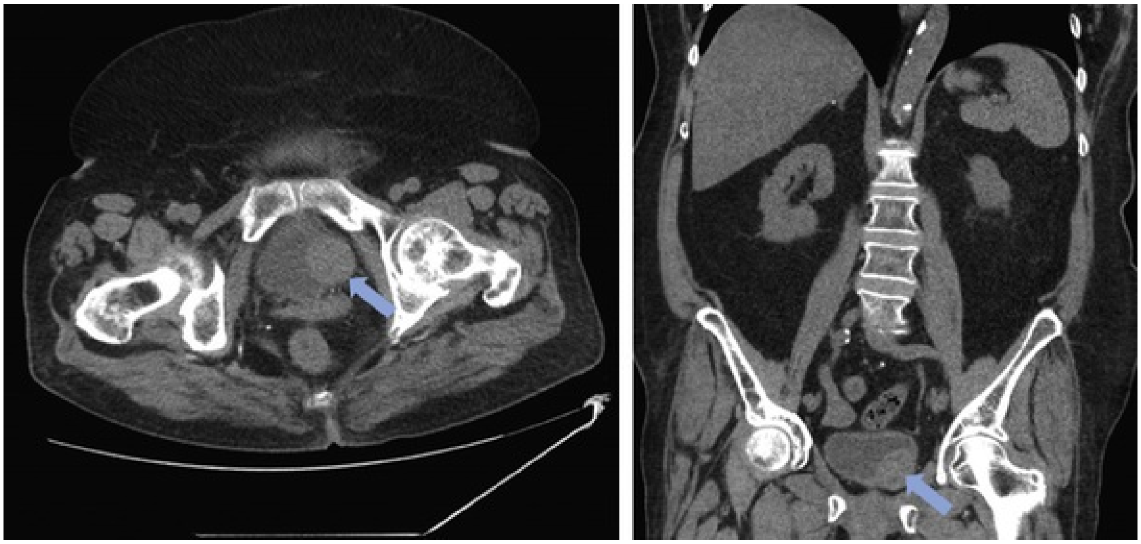

FIG. 132.31 Bladder leiomyoma. Computed tomography scan demonstrating a well-circumscribed extraluminal lesion *(arrow)* invested within the detrusor muscle. Resection of the lesion demonstrated a leiomyoma. (Courtesy of Lee Richstone, MD.)

Paraganglioma

Paragangliomas, which represent extra-adrenal tumors originating from chromaffin cells of the sympathetic nervous system, occur most commonly along the sympathetic chain, although benign tumors of the bladder have been described (Leestma and Price, 1971). The majority exhibit functional properties related to the release of catecholamines and thus may manifest with episodic bouts of hypertension, tachycardia, palpitations, diaphoresis, or tremors. Unique to bladder wall paragangliomas is the occurrence of hypotension and syncope related to micturition or sexual activity (Al-Zahrani, 2010).

Despite the functional properties of these tumors, bladder wall paragangliomas often present with nonspecific symptoms such as painless hematuria or may be recognized incidentally on cross-sectional imaging as a bladder wall thickening (Leestma and Price, 1971). In this context, bladder instrumentation or transurethral manipulation of these tumors without appropriate preoperative alpha-adrenergic blockage, particularly in asymptomatic patients, may result in a dangerous intraoperative catecholamine surge (Chen et al., 2009). As such, a preoperative workup involving measurement of plasma metanephrines and functional imaging of the bladder lesion is necessary if these tumors are suspected (Fig. 132.32).

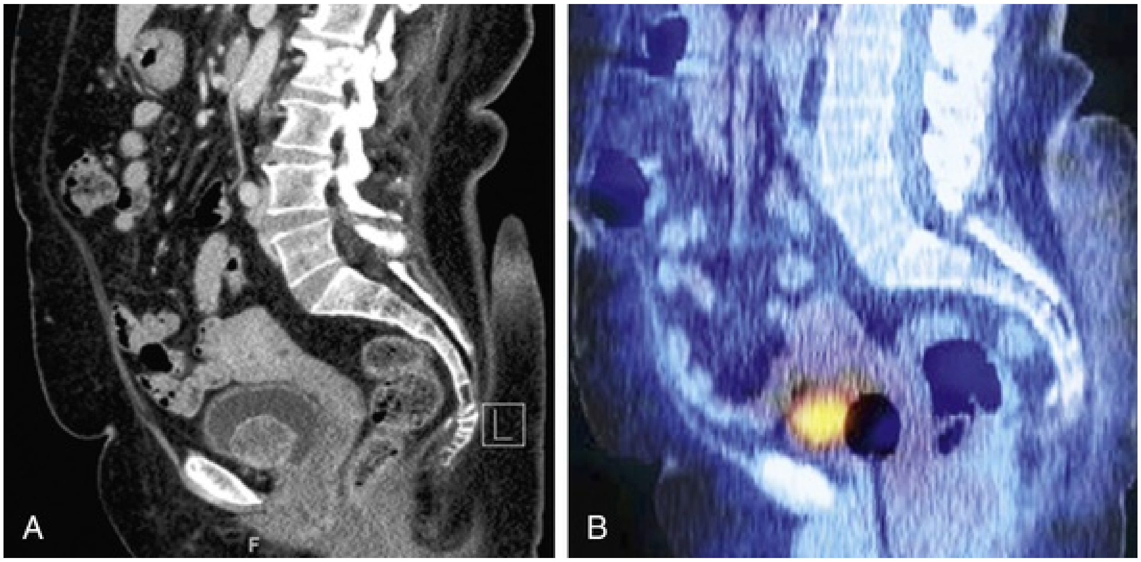

FIG. 132.32 Bladder paraganglioma. (A) A bladder mass seen at base of bladder on sagittal computed tomography. (B) Positive metaiodobenzylguanidine (MIBG) scan confirming functional bladder mass, consistent with paraganglioma. (Modified from El-Tholoth HS, Al Rasheedi S, Alharbi F, et al. Paraganglioma of urinary bladder managed by laparoscopic partial cystectomy in conjunction with flexible cystoscopy: a case report. *J Endourol Case Rep* 4(1):15–17, 2018.)

Cystoscopically, paragangliomas appear as yellow regions of raised mucosa as they tend to be situated within the detrusor muscle (Al-Zahrani, 2010). Partial cystectomy is preferred over transurethral resection, including for benign lesions, as there is a high tendency for local recurrence in cases of inadequate extirpation (Dahm and Gschwend, 2003).

Endometriosis

Endometriosis of the bladder can be primary in nature or occur secondary to iatrogenic dissemination during pelvic surgery (Vercellini et al., 2002). Classical symptoms include cyclic patterns of hematuria or irritative voiding symptoms that coincide with menses. As ectopic involvement of the bladder by endometrial tissue is generally extravesical in nature, cystoscopy is of limited utility in the evaluation of these patients, although it does enable assessment for mucosal involvement. Instead, transabdominal ultrasonography, often coupled with transvaginal ultrasonography can help gauge lesion size and degree of bladder involvement. MRI may also help delineate the level of disease (Fig. 132.33) (Beaty et al., 2006). Partial cystectomy is the primary form of treatment for these lesions, again given the extravesical pattern of distribution (Komar, 2004).

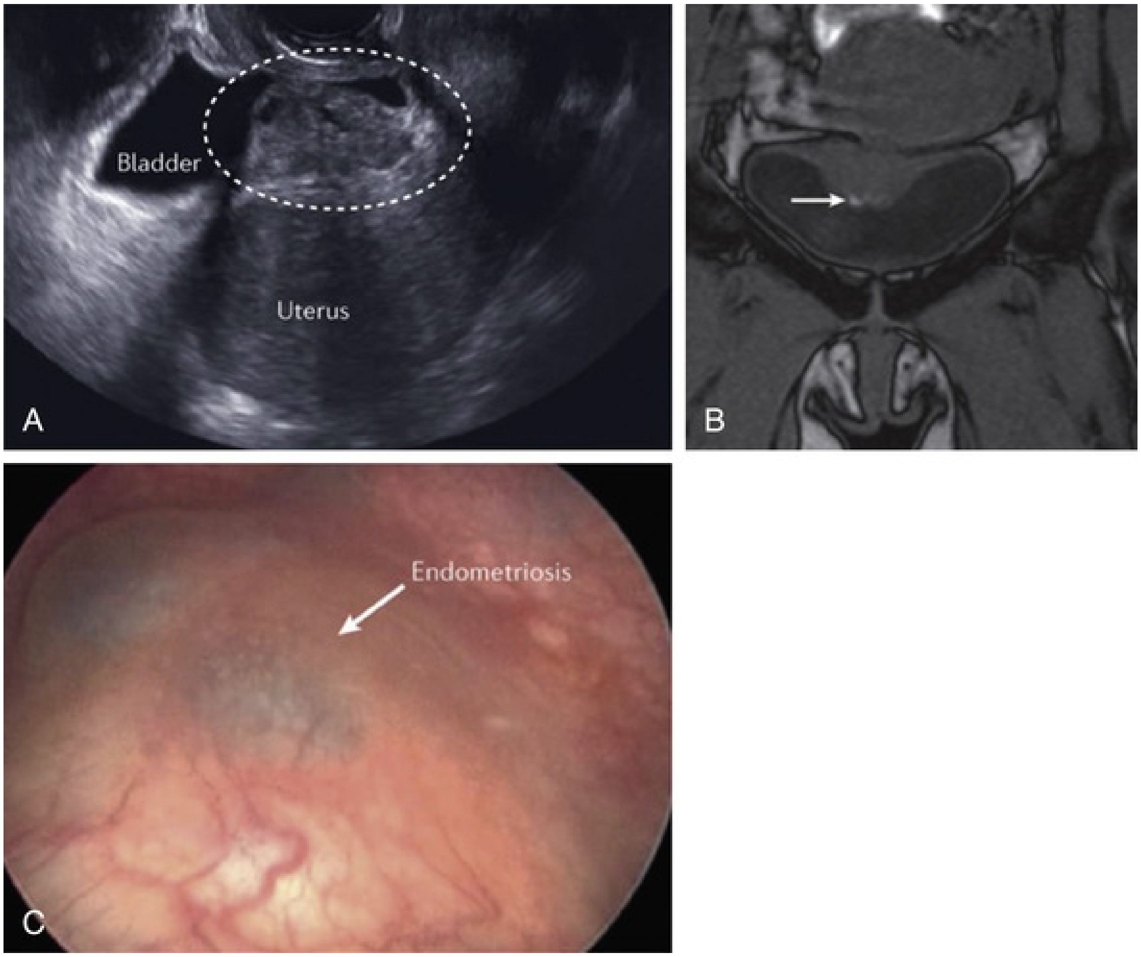

FIG. 132.33 Bladder endometriosis. (A) Ultrasound scan demonstrating deeply infiltrative mass protruding into bladder lumen, appearing contiguous with the uterus. (B) T1-weighted imaging demonstrating high signal intensity within the mass *(arrow),* consistent with bladder endometriosis. (C) Endometriosis situated in the detrusor fibers of the bladder wall, appearing as a submucosal bladder lesion with a bluish hue and neovascularization. (Modified from Nezhat C, Falik R, McKinney S, et al. Pathophysiology and management of urinary tract endometriosis. *Nat Rev Urol* 14[6]:359–372, 2017.)

Urachal Abnormalities

The urachus is the embryologic remnant of the allantois and provides ligamentous support from the dome of the bladder to the umbilicus. Benign pathology related to the urachus are most frequently encountered in the pediatric population, although delayed onset of symptoms may cause clinical manifestations in adults (Berman et al., 1988). The primary benign urachal conditions seen in adults that may warrant partial cystectomy include urachal cysts, vesico-urachal diverticula, a patent urachus, and urachal sinus (Berman et al., 1988; Sheldon et al., 1984). Communication with the bladder, as is seen for vesico-urachal diverticula and parent urachus, may result in hematuria, mucinuria, or urine leakage from the umbilicus. Nonspecific symptoms resulting from either of these conditions include fever, abdominal pain, or peri or infraumbilical fluctuant mass secondary to infection of stagnant urine or fluid (Blichert-Toft and Nielsen, 1971). Less often, a calculus may form. The gravest of concerns relates to malignant transformation of remnant urachal tissue (Herr, 1994).

As the majority of urachal anomalies are asymptomatic, they are often incidentally detected on cross-sectional imaging. When symptomatic, they can be evaluated using ultrasonography or CT (Fig. 132.34A). A VCUG or sinogram may be performed to evaluate communication with the bladder, particularly in cases of urinary symptoms or skin drainage. The bladder dome and anterior bladder wall should be carefully inspected to ensure that no suspicion lesions are present (see Fig. 132.34B).

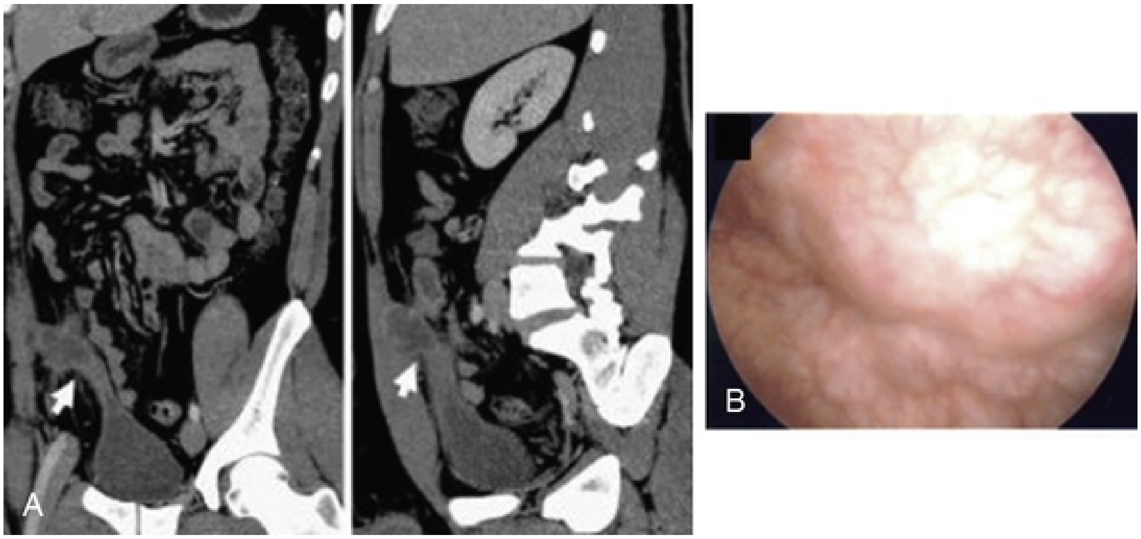

FIG. 132.34 (A) Contrast-enhanced computed tomography scan demonstrating heterogenous enhancing lesion posterior to the abdominal wall with tubular connection to the bladder dome. The lesion was found to be an infected urachal remnant on resection. (B) Submucosal bladder dome lesion protruding into the lumen is found to be a urachal cyst. (A, Modified from Liu WC, Hsiang CW, Hsu HH, et al. An infected urachal remnant in a young man. *Intern Med* 53[5]:523, 2014; B, Modified from Madeb R, Knopf JK, Nicholson C, et al. The use of robotically assisted surgery for treating urachal anomalies. *BJU Int* 98[4]:838–842, 2006.)

Treatment is indicated for symptomatic or infected urachal anomalies. In the setting of inflammation or infection, patients should be treated with oral or intravenous antibiotics. Swab culture of the umbilicus and urine cultures should be sent before initiating antibiotics. In the setting of a fluctuant umbilicus, local incision and drainage can be performed. If the infection resolves with complete relief of symptoms, no further intervention is required. In the setting of recurrent infected urachal anomalies, surgical excision is indicated (Navarrete et al., 2005; Stone et al., 1995; Yohannes et al., 2003b). The entire urachus should be excised including a small area on the dome of the bladder. The practice of incorporating a bladder cuff into the surgical specimen is thought to ensure that no residual tissue is left in the vicinity of the bladder apex as this may risk recurrence of symptoms or malignant transformation.

Surgical Technique

Open partial cystectomy remains most widely used for treatment of select bladder tumors given the accrued experience with this approach. However, use of laparoscopic and robotic techniques have gained significant momentum in the management of not only bladder and urachal malignancies, but also benign bladder processes as they represent a particularly attractive low-morbidity alternative to open surgery for lesions that require more extensive resection than can be safely achieved by endoscopic means (Cadeddu et al., 2000; Madeb et al., 2006; Mettler et al., 2008).

Open

The approach to partial cystectomy is contingent on the location of the lesion to be resected. Lesions on the dome or anterior bladder wall are amenable to an extraperitoneal approach, whereas tumors situated along the posterior bladder wall are better managed with an intraperitoneal approach.

Extraperitoneal Approach to Partial Cystectomy

The initial steps to extraperitoneal open partial cystectomy are similar to open ureteral reimplantation (described earlier), including patient positioning, preparation, initial incision, and extraperitoneal bladder mobilization. A pelvic lymph node dissection is usually not necessary for benign indication and thus can be deferred at this time. With the bladder having been adequately mobilized bilaterally, intraoperative cystoscopy is performed to confirm the location of a lesion, particularly if found to be situated intravesically on preoperative evaluation. For conditions that are primarily extravesical or submucosal within the detrusor, intraoperative ultrasonography can be used to help demarcate the location and extent of the lesion.

Stay sutures are placed on the bladder wall distant from the location of the lesion, and a longitudinal cystotomy is made to gain access to the bladder. The bladder may be partially distended as the cystotomy is made, although it is critical that the intravesical fluid be aspirated so as to avoid spillage into the field because even some benign processes have a tendency for local recurrence. The cystotomy incision is lengthened enough to provide good visualization of the site of bladder pathology. Before resection, careful inspection of the bladder mucosa is necessary to rule out presence of any abnormalities concerning malignancy.

Once the borders of the lesion are defined, a circumferential transmural incision is made around the lesion with electrocautery. Despite this being a benign process, a margin of normal bladder wall is necessary as some disease processes have a high tendency to recur in the setting of inadequate resection. Additionally, the perivesical fat overlying the lesion should be preserved. If the bladder capacity permits, we recommend a 2-cm margin of normal tissue. Biopsies of the normal appearing bladder wall should be taken to ensure adequate resection.

In cases in which the lesion encroaches on or involves the ureteral orifice, the ureter should be mobilized and reimplanted in a refluxing or nonrefluxing manner as described earlier.

The bladder wall defect is subsequently closed in a two-layer running fashion with 2-0 polyglactin suture, ensuring proper mucosal apposition with the first layer of closure. The cystostomy is subsequently closed in a similar fashion.

A perivesical drain is placed in the retropubic space, ideally crossing over the bladder wall defect and cystotomy site. This is brought out through a separate stab incision lateral to the rectus muscle and secured to the skin with nonabsorbable suture. A 22-Fr Foley catheter is left in place within the bladder. The bladder should be irrigated to assess adequacy of closure. The abdominal fascia and incision are closed in the usual fashion.

Transperitoneal Approach to Partial Cystectomy

After incising the transversalis fascia, the peritoneum is entered sharply in the midline and opened the length of the incision. A self-retaining retractor is placed and used to pack the abdominal content cephalad to provide access to the peritoneal fold overlying the dome of the bladder. The space of Retzius and lateral pelvic gutters are developed with blunt dissection.

Mobilization of the ureter is often necessary as partial cystectomy of the posterior bladder wall may necessitate ureteral reimplantation. The peritoneum overlying the bifurcation of the iliac vessels is incised, and the ureter is identified. The ureter is dissected caudally toward its entry into the bladder. Care is taken to preserve the periureteral tissue, which harbors the periureteral blood supply.

The posterior bladder is mobilized enough to support adequate resection of the tumor. In women, this may involve incision of the peritoneal fold overlying the vesicoureterine pouch and development of the pubocervical fascia with sharp dissection. In men, the peritoneum of the rectovesical pouch may be incised to develop Denonvillier's fascia, particularly for very posteriorly situated lesions near the bladder base.

Resection of the lesion is performed in a manner similar to the extraperitoneal approach described earlier.

Urachal Surgery

In cases in which partial cystectomy is being performed as part of resection of the urachal remnant, an initial periumbilical incision is made that is carried down the midline. After incision of the tranversalis fascia, the peritoneum is identified. A circumferential incision is made around the umbilicus at the level of the skin down to the peritoneum. The peritoneal cavity is entered sharply above the umbilicus. With anterior traction placed on the umbilical segment, the urachus is excised with generous peritoneal wings down to the level of the bladder dome. The bladder is distended with sterile water to facilitate a transmural incision in the apical bladder dome circumferentially around insertion of the urachus into the bladder. A wide margin of resection around the site of urachal insertion is not necessary for benign indication. The bladder wall defect is subsequently closed in a two-layer manner with 2-0 polyglactin suture. A large-bore Foley catheter and pelvic drain are placed, as described earlier. The bladder should be irrigated to assess adequacy of closure.

Of note, when the urachal remnant is being excised for infection or inflammation, if proper incision and drainage of any subcutaneous fluid has been performed, it is unnecessary to remove the umbilicus in the absence of malignancy.

Laparoscopic and Robotic Techniques

Transperitoneal Approach to Partial Cystectomy

Positioning and port placement in patients undergoing laparoscopic or robotic partial cystectomy is similar to that for robotic diverticulectomy (see Fig. 132.10).

The bladder is first mobilized off the anterior abdominal wall, and the space of Retzius is accessed by incising lateral to the obliterated umbilical ligaments and transecting the urachus. Once the bladder is mobilized, the bedside assistant performs flexible cystoscopy to transilluminate the bladder and allow the surgeon to delineate the site of bladder pathology from an intraperitoneal perspective (Fig. 132.35). The robotic/laparoscopic intraperitoneal light is dimmed to aid in visualization. For tumors situated along the posterior bladder wall, the bladder does not need to be mobilized off the anterior abdominal wall; instead, intraoperative cystoscopy can help identify the site of pathology with the bladder suspended, and the peritoneum directly overlying this region of disease is dissected. Lesions situated intramurally or on the extravesical surface of the bladder may be characterized with a laparoscopic ultrasound instrument.

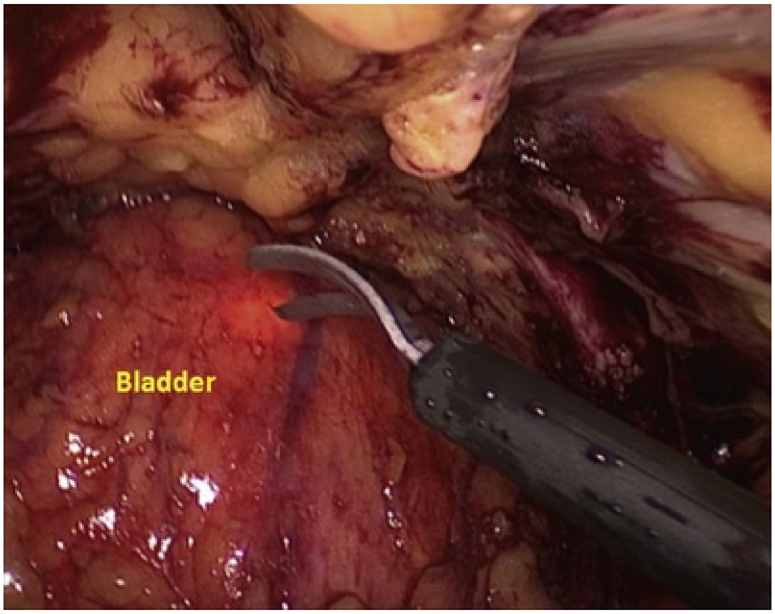

FIG. 132.35 Intraoperative cystoscopy to delineate bladder lesion from transperitoneal view and help guide location for cystotomy. (Modified from El-Tholoth HS, Al Rasheedi S, Alharbi F, et al. Paraganglioma of urinary bladder managed by laparoscopic partial cystectomy in conjunction with flexible cystoscopy: A case report. *J Endourol Case Rep* [1]:15–17, 2018.)

Electrocautery can be used to outline the area of resection on the outside of the bladder to ensure that adequate margins of resection are achieved. When electrocautery is complete, the cystoscope is removed, and a Foley catheter is placed. The Foley catheter is plugged to permit bladder distension.

With the bladder distended, a longitudinal cystotomy is made superior/anterior to the identified lesions, and the bladder is entered. Care should be taken to aspirate fluid within the bladder as it is entered to avoid spillage of intravesical contents. The Foley balloon is taken down, and the bladder mucosa is inspected. The site of the bladder lesion is noted as is the proximity to the ureteral orifices. A ureteral catheter may be placed retrograde at this time to help protect the ureter. Alternatively, if there is concern over ureteral disruption, reimplantation may be pursued after resection of the lesion.

Using electrocautery, full-thickness resection of the lesion is carried out circumferentially via an intravesical perspective (Fig. 132.36). The perivesical fat overlying the lesion should be preserved. Attempts should be made at attaining an adequate margin of normal-appearing bladder mucosa given the propensity for some lesions to locally recur in cases of inadequate resection. Once disconnected from the bladder, the specimen is placed into a 10- or 15-cm EndoCatch bag. Frozen sections of the resection margins may be performed to ensure adequacy of excision. A large-bore Foley catheter is placed, and the bladder wall defect and the cystotomy are closed in the standard two-layer fashion using 2-0 polyglactin suture. The bladder is filled with 200 mL of sterile water to test the adequacy of closure; defects in the closure can be reinforced with full-thickness figure-of-eight 2-0 polyglactin suture.

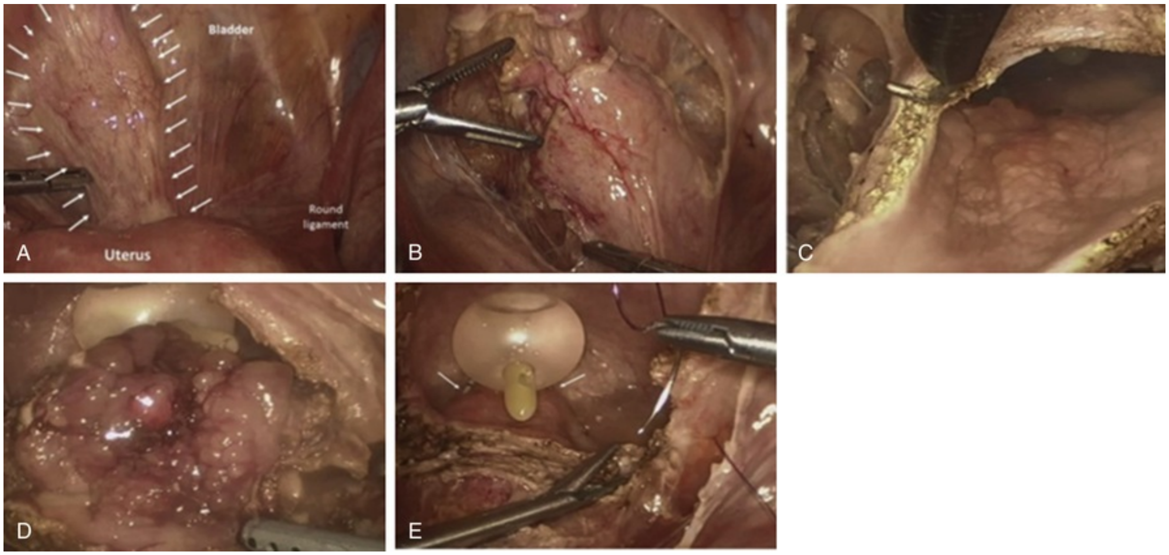

FIG. 132.36 Laparoscopic partial cystectomy. (A) The location of the bladder pathology is identified along the posterior-lateral dome of the bladder. (B) Given the posterior location of the lesion, the bladder was left suspended to the anterior abdominal wall. The peritoneum around the area of the lesion is incised. (C) A cystotomy is made to allow a normal margin of tissue around the lesion, and circumferential incision is commenced. (D) Posterior attachments of lesion to the bladder wall are excised. (E) The bladder wall defect is closed in two layers. The ureteral catheters can be visualized *(white arrow).* (Modified from Koukoura O, Alevra Z, Pavlakis K, Pistofidis G. Laparoscopic excision of an inflammatory myofibroblastic tumour of the bladder disguised as deep infiltrating endometriosis. *BMJ Case Rep* 2017.)

A pelvic drain is placed in the vicinity of the bladder wall closure and brought out through the lateral port. It is secured to the skin with nonabsorbable suture and placed to self-suction. The pneumoperitoneum is released. The specimen is extracted through an extension of the midline camera-port incision. The fascia of the extraction site and the fascia of the 12-mm assistant port are closed with figure-of-eight 0-polyglactin suture. Skin incisions are closed.

Urachal Surgery

When performing partial cystectomy as part of surgery to remove the urachal remnant, the 12-mm camera port is inserted 5 cm above and 2 cm to the left of the umbilicus. In contrast with conventional open surgery, the urachus is dissected out last when performing partial cystectomy for urachal disease. The laparoscopic/robotic surgeon should leave the bladder attached to the anterior abdominal wall during the initial dissection to maximize visualization and exposure. The bladder can be filled with approximately 200 to 300 mL of sterile water to better define the anatomy.

Using electrocautery, a small rim of bladder segment around insertion of the urachus is scored, and dissection proceeds through all layers of the bladder with the exception of the bladder mucosa. Before dividing the bladder mucosa, the entire urachus with peritoneal wings is dissected all the way to the level of the umbilicus. The urachus is divided at this level, and the umbilicus can be removed at the end of the case if necessary, although it is not required for benign indication. When the entire urachus is dissected free, the bladder is opened, and the bladder wall is excised circumferentially around the site of urachal insertion (Fig. 132.37). The specimen is placed in an EndoCatch bag. Frozen section of the bladder wall resection margin is not necessary for benign indication.

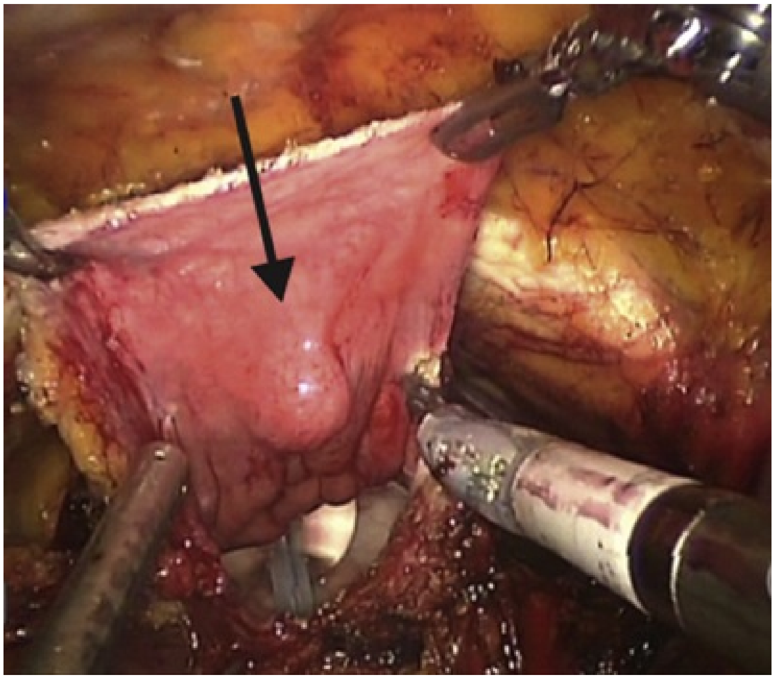

FIG. 132.37 Laparoscopic resection of urachal anomaly *(arrow).* (Modified From Kim DK, Lee JW, Park SY, et al. Initial experience with robotic-assisted laparoscopic partial cystectomy in urachal disease. *Korean J Urol* 51[5]:318–322, 2010.)

The bladder is closed in two layers using 2-0 polyglactin suture. A large-bore Foley catheter is placed, and the closure is tested with instillation of 200 mL of sterile water. A pelvic drain is placed and brought out to the skin through the lateral port. The specimen is extracted through an extension of the midline camera-port incision. In some cases, the specimen bag may be removed directly through the lateral 12-mm assistant port without the need for extending the midline incision. The fascia, including that of the 12-mm assistant port, is closed with figure-of-eight 0-polyglactin suture. Skin incisions are closed.

Postoperative Care and Complications

The Foley catheter is kept to drainage for approximately 1 week postsurgery with a cystogram performed before removal. The pelvic drain is removed typically after 48 hours once the output has decreased; a drain creatinine measurement is optional and should be interpreted in the context of the drain output.

Complications after partial cystectomy are similar for both open and minimally invasive techniques and essentially mimic those seen for bladder diverticulectomy (see earlier discussion). Urinary extravasation from either the site of resection or cystotomy is the most common complication, followed by ureteral injury. A full description of the presentation and management of these complications is provided earlier in this chapter in the Bladder Diverticulectomy section.

Patient selection and counseling regarding complications is important as resection of bladder wall segment can decrease bladder capacity and cause irritative voiding symptoms that may require future intervention. Other complications include urinary tract infection, bladder spasms, urinary fistula formation, wound infection, and bowel injury.

Outcomes

Experience with treatment of benign bladder tumors and urachal lesions using partial cystectomy are generally limited to small case series given the rarity of these conditions in adults. Nevertheless, partial cystectomy, performed using conventional open techniques or a minimally invasive platform, has demonstrated considerable success in management of the pathologies mentioned earlier, offering high rates of cure while enabling preservation of bladder function (Albert, 1981; Cadeddu et al., 2000; Madeb et al., 2006; Mettler et al., 2008).

Bladder Stones and Foreign-Body Removal

Description

Bladder calculi, although encountered far less frequently than kidney and ureteral stones, represent a distinct pathologic entity with substantial potential to disrupt quality of life. The primary biologic underpinning of bladder stone formation is thought to be urinary stasis; as such, bladder calculi are encountered most often in the setting of either bladder outlet obstruction syndromes, particularly benign prostate hyperplasia in men, or neurogenic bladder. Less commonly, bladder calculi can form in the setting of bladder substitution or augmentation with bowel, as a result of a multitude of factors including incomplete emptying and associated stasis, high bacterial burden within the urinary system, metabolic alterations in urinary composition, and possibly increased mucus production. The presence of foreign body within the bladder, usually introduced via an iatrogenic route, may also serve as a nidus for stone formation.

Evaluation and Surgical Indication

As the majority of bladder stones are asymptomatic, incidental detection is often the case during diagnostic workup for associated conditions. Alternatively, symptoms such as hematuria, irritative voiding patterns, recurrent urinary tract infections, incontinence, or urinary retention may prompt cystoscopy or imaging of the bladder, at which time bladder stones may be discovered as offending agents.

Before surgical intervention for bladder stones, a proper diagnostic evaluation should be undertaken to not only characterize stone burden, as this will inform the most appropriate management strategy, but also understand concomitant conditions ultimately responsible for stone formation. This will enable the implementation of strategies to prevent reoccurrence of bladder stones and aid in operative planning, particularly if a concomitant procedure to address the underlying cause is necessary.

Noncontrast CT provides the most reliable assessment of stone volume and stone size, of which accurate measurement is critical given their role in guiding treatment selection. Additionally, cross-sectional imaging with CT may help understand anatomy as it relates to underlying disease states associated with bladder stone formation, such as prostate volume in the case of BPH, or presence of hydronephrosis in the setting of neurogenic bladder. Cystoscopy for direct visualization of bladder stones before procedural intervention is not necessary unless indicated for other reasons, such as gross hematuria, concern for bladder malignancy, or anatomic evaluation of prostatic lobar hyperplasia and prostatic urethral length. Before treatment of bladder stones, urodynamics may be utilized if neurogenic bladder is suspected or as part of treatment planning in individuals with BPH.

Surgical Technique

Open cystolithotomy has historically served as the gold standard procedure for management of bladder calculi. Transurethral and more recently percutaneous endoscopic techniques, however, have largely supplanted this approach in contemporary practice primarily because of perceived advantages in cosmesis and duration of postprocedural catheterization times. Nevertheless, relatively large-sized bladder calculi or high-volume stone burden may be best managed by cystolithotomy to maximize the chance for stone-free outcome and minimize operative duration, particularly as prolonged transurethral instrumentation can pose a risk for urethral stricture.

The nature of simultaneous procedures planned for associated disease states should also be factored in when deciding treatment approach for bladder stones. For example, a very enlarged prostate gland that is not amenable to transurethral resection or vaporation may be better managed with a simple prostatectomy, ideally through a transvesical route; in this case, cystolithotomy may be preferred to manage bladder stones in tandem. A large bladder diverticulum necessitating diverticulectomy to diminish risk for urinary stasis may also encourage the use cystolithotomy. In patients with neurogenic bladder who have evidence of poor compliance that is refractory to conservative measures such as anticholinergic therapy or intravesical botulinum toxin injection, enterocystoplasty may be considered, at which time cystolithotomy may be performed.

Additional considerations involve history of prior bladder or abdominal surgery as alterations in the local pelvic anatomy may preclude percutaneous approaches for larger stones over concern of bowel injury during initial puncture and establishment of the access tract. This is particularly relevant among individuals with bladder stones in the setting of a urinary diversion or augmented bladder.

The laparoscopic and robotic techniques that have emerged for cystolithotomy offer a minimally invasive alternative to the traditional open approach while not compromising on the ability to remove larger stone burden. Improved experience, particularly with minimally invasive approaches to transvesical simple prostatectomy and bladder diverticulectomy, makes this an attractive option for addressing bladder stones when multiple procedures are necessary in a single-stage setting.

Percutaneous cystolithotripsy offers another minimally invasive option for the management of large bladder calculi. Access into the bladder via a single small suprapubic incision enables enhanced cosmesis relative to open cystolithotomy and offers lower morbidity given the creation of a smaller cystotomy when compared with open and laparoscopic procedures. Shorter catheterization time and hospital stay have also been reported for the percutaneous technique (Demirel et al., 2006). Furthermore, the larger diameter of the nephroscope and its wider working channel improves visualization and allows for use of a versatile array of instruments that permit more efficient stone fragmentation over shorter operative durations when compared with conventional transurethral cystoscopic procedures (Aron et al., 2003). In this regard, the percutaneous approach to endoscopic bladder stone surgery virtually eliminates the risk for urethral stricture disease, which has been reported after prolonged urethral instrumentation time during transurethral cystolitholapaxy.

In addition to bladder stones, foreign bodies within the bladder can be removed using open techniques as well laparoscopically, via a transperitoneal or transvesical LESS approach, or robotically. Procedures for removal of foreign bodies have been described for objects including surgical materials and mesh (Kim et al., 2012; Macedo et al., 2013; Maher and Feiner, 2011; Roslan et al., 2013; Yoshizawa et al., 2011), migrated intrauterine devices, broken sewing needles (Lee et al., 2010), and electrical wires (Ko et al., 2010).

Open

The patient is placed in a supine position with the anterior superior iliac spine positioned over the break of the table. The table is placed into slight flexion to facilitate entry into the space of Retzius (see Fig. 132.5A). The genitalia and intraumbilical aspect of the abdomen is prepped and draped in the standard sterile fashion. An 18-Fr Foley catheter is placed into the bladder on the sterile field. The bladder is distended with approximately 200 mL of sterile water, and the catheter is plugged.

Using either a midline infraumbilical incision (see Fig. 132.5B) or transverse Pfannenstiel incision, the subcutaneous tissue is divided with electrocautery down to the level of the rectus fascia. The type of incision used to access the extravesical space depends in part on whether additional procedures will be performed concomitantly, such as bladder diverticulectomy or simple prostatectomy.

The rectus fascia is divided the length of the incision exposing the underlying rectus abdominus muscle. The bellies of the rectus abdominus muscle is split longitudinally at the midline, and the space of Retzius is developed with blunt dissection. Distension of the bladder displaces the peritoneal reflection cephalad and permits easier entry into the space of Retzius. Extensive mobilization of the bladder from lateral perivesical attachments is not necessary.

With the bladder distended, electrocautery is used to make a vertical cystotomy across the midline bladder dome toward the bladder neck (Fig. 132.38A). Fluid within the bladder is aspirated as the cystotomy is lengthened. A 2-0 polyglactin stay suture is placed transmurally at the apices of the cystotomy to prevent tearing of the bladder wall as the bladder is accessed. Deeper blades can be placed on the self-retaining retractor to gently retract the bladder walls and facilitate exposure; alternatively, this can be done with a handheld deep blade retractor.

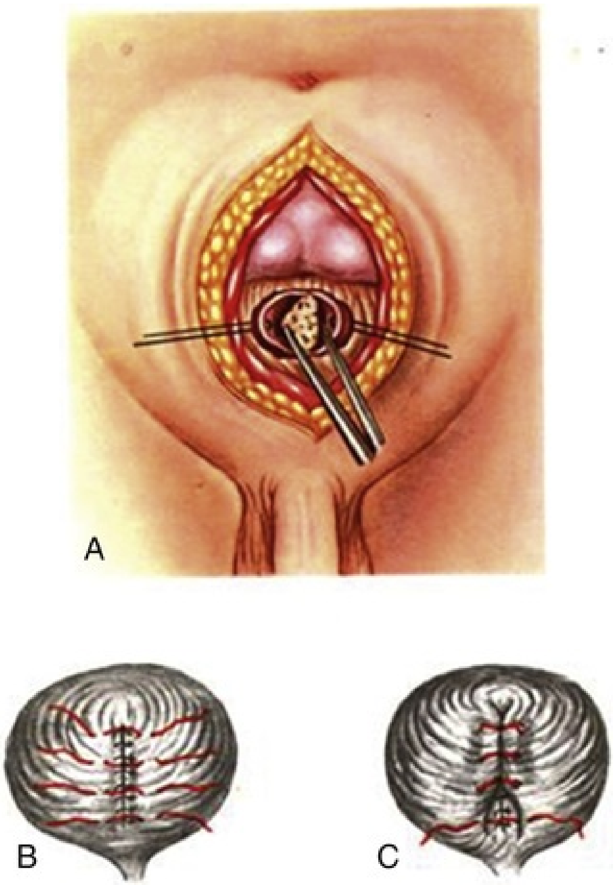

FIG. 132.38 Open cystolithotomy. (A) A vertical cystotomy is made on the bladder dome allowing access to the bladder. The calculus is visualized and removed. (B) A two-layer closure is done, beginning with the mucosal layer. (C) Imbricating sutures are used to perform the second layer of closure and bury the mucosal closure sutures.

Bladder stones (or other foreign bodies) are removed under direct visualization. The bladder should be inspected to characterize any suspicious mucosal lesions and the presence of intravesical prostatic lobe, which may be causing outlet obstruction. Any additional procedures to address outlet obstruction (e.g., suprapubic prostatectomy) or urinary stasis (e.g., diverticulectomy) can be performed at this time.

A large-bore catheter is placed to facilitate postoperative drainage. The bladder is closed in a two-layer running fashion using 2-0 polyglactin suture (see Fig. 132.38B,C). A suprapubic catheter may be placed before closure, although this is not necessary. After bladder wall closure, a pelvic drain is situated anterior to the cystostomy in the retropubic space and secured to the skin placed to self-suction. The fascia is closed with 0-loop polydioxanone suture after which the skin is closed.

Laparoscopic and Robotic

A transperitoneal approach is the most straightforward technique to laparoscopic and robotic cystolithotomy or foreign-body excision. Patient positioning and port placement are similar to that described in Fig. 132.10 (Macedo et al., 2013; Maher and Feiner, 2011). A fourth robotic arm is not necessary and is up to the discretion of the surgeon.

The bladder is mobilized off the anterior wall as described earlier. An anterior vertical or transverse cystotomy is made with electrocautery, and the bladder stone or foreign body is visualized. Ureteral catheterization is performed if needed, and the bladder stone or foreign body is removed or excised. The bladder is closed in a two-layer fashion with 2-0 polyglactin suture (Fig. 132.39). A large-core Foley catheter is placed, and the closure is tested with instillation of fluid. A pelvic drain is placed over the cystotomy and placed to self-suction.

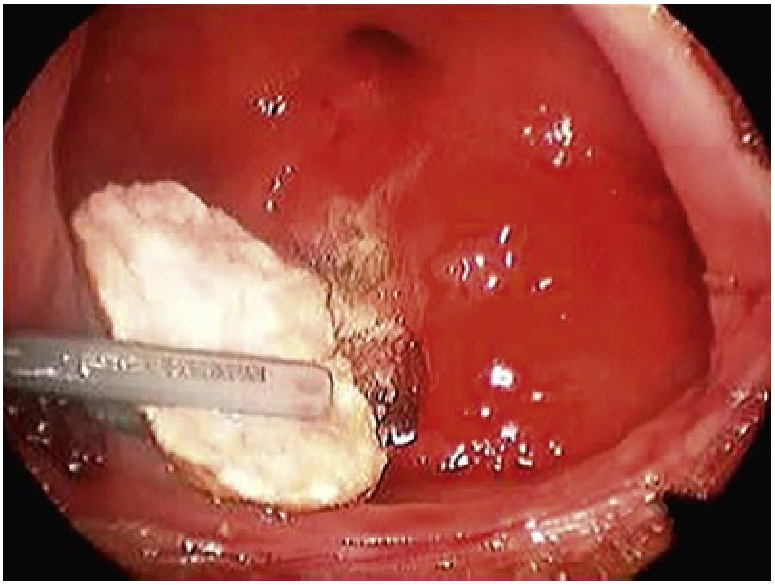

FIG. 132.39 Transperitoneal laparoscopic mesh excision. After establishment of pneumoperitoneum, transabdominal trocars are placed via traditional techniques. The bladder is opened, and mesh, stones, or foreign bodies are removed. The bladder is closed in two layers with absorbable sutures. An intravesical mesh is shown with associated large bladder calculi.

The abdominal cavity can be avoided by using a transvesical approach, which can be performed with multiple trocars (Fig. 132.40) (Kim et al., 2012; Yoshizawa et al., 2011). After cystoscopy and saline instillation into the bladder, a 5-mm trocar is placed into the bladder under direct vision, the bladder is drained, and pneumovesicum is established at 8 to 12 mm Hg. Two additional trocars are placed, and the bladder stone is removed or the foreign body is excised.

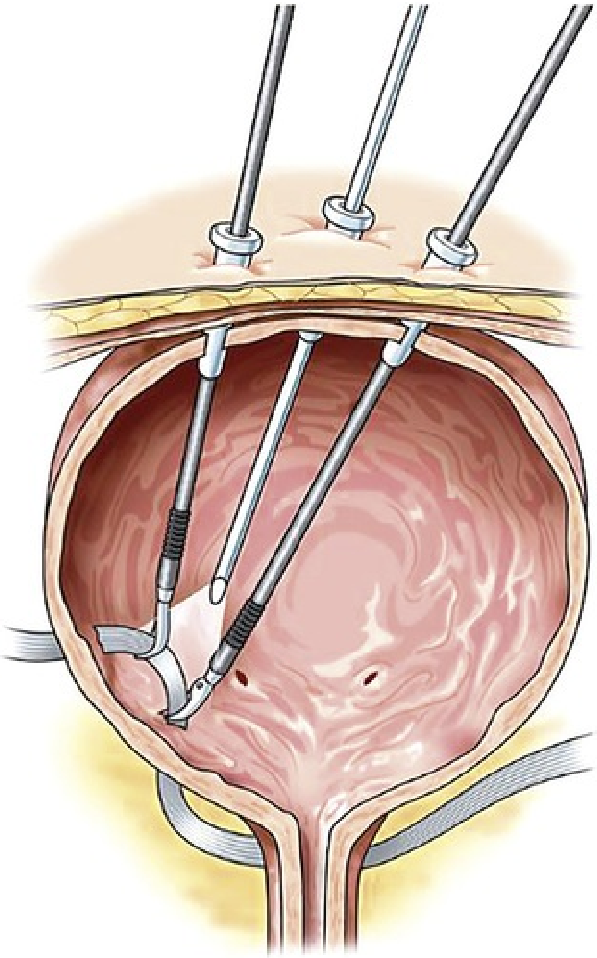

FIG. 132.40 Transvesical laparoscopic mesh excision. After cystoscopy, transvesical trocars are placed directly into the bladder. Pneumovesicum is established and maintained. Mesh or other foreign bodies are excised, and the bladder is closed with absorbable suture. (Modified from Yoshizawa T, Yamaguchi K, Obinata D, et al. Laparosocopic transvesical removal of erosive mesh after transobturator tape procedure. *Int J Urol* 18[12]:861, 2011.)

Transvesical excision of foreign bodies and/or mesh also can be performed via a transvesical single-site method (Fig. 132.41) (Ingber et al., 2009; Roslan et al., 2013). After cystoscopy and saline instillation, a single-site device is deployed, and the foreign body is identified and excised followed by bladder closure. To aid in retraction, a grasper can be placed transurethrally (Roslan et al., 2013).

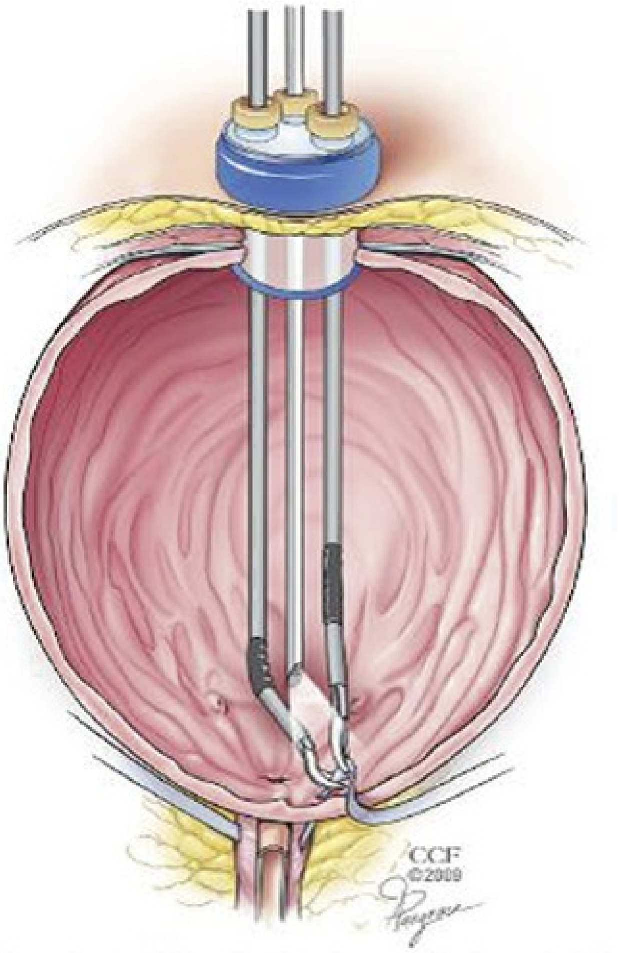

FIG. 132.41 Transvesical single-site mesh excision. After cystoscopy, the bladder is distended with saline. A single-site access port is placed directly in the bladder, and pneumovesicum is established. Transvesical single-site mesh excision is performed, and the bladder is closed. (From Ingber MS, Stein RJ, Rackley RR, et al. Single-port transvesical excision of foreign body in the bladder. *Urology* 74[6]:1347–1350, 2009.)

Percutaneous

The patient may be placed in either a dorsal lithotomy or supine position. The perineum and lower abdomen are prepped and draped, ideally with an apparatus that has a fluid control pouch.

A Foley catheter is placed transurethrally, and the bladder is distended with 300 mL of sterile saline. A 1-cm skin incision is made approximately two fingerbreadths above the pubic symphysis. An 18-gauge trocar needle placed through the incision is used to puncture into the bladder. This step may be done under ultrasound guidance. Alternatively, access into the bladder may be established under direct visualization with flexible cystoscopy. In patients with a prior history of abdominal surgery, preoperative cross-sectional imaging or real-time ultrasound may be performed to ensure that there is no interposing bowel segment between the skin and bladder.

The inner obturator of the needle is removed to evaluate for the return of urine, which confirms access into the bladder. An Amplatz Super Stiff polytetrafluoroethylene-coated 0.038-inch J-tip guidewire (Boston Scientific, Marlborough, MA) is cannulated through the needle trocar to allow curling within the bladder, after which the trocar is subsequently removed over the wire. Amplatz renal dilators (Cook Medical, Bloomington, IN) are introduced over the wire and used to sequentially dilate the percutaneous tract up to 30 Fr. A 30-Fr sheath is positioned across the suprapubic percutaneous tract through which a 24-Fr or 26-Fr nephroscope is inserted. The wider caliber of the access sheath relative to the nephroscope permits continuous bladder irrigation and thus aids in visualization.

For stones less than 1 cm, a rigid grasping forceps can be used to retrieve the stone without the need for fragmentation. Alternatively, larger stones may be fragmented or comminuted with a pneumatic or ultrasonic lithotripter under direct visualization through the nephroscope. A rigid grasping forceps can be used subsequently to grasp residual stone fragments.

Once the stone burden has been adequately cleared, a suprapubic catheter is inserted into the bladder over the guidewire and placed to gravity drainage. Alternatively, a large-bore transurethral Foley may be placed in lieu of a suprapubic tube.

Tan et al. (2014) reported on the use of a laparoscopic entrapment bag to aid in stone sequestration and clearance during percutaneous cystolithotripsy. In a series of 21 patients, the authors introduced a laparoscopic entrapment bag into the bladder through the 30-Fr Amplatz access sheath. With the aid of a flexible cystoscope, the bag is maneuvered intravesically to capture the stone(s). The bag is cinched and exteriorized to the level of the skin with the Amplatz sheath removed. The bag, which now carries the stone within it, is opened, and the 30-F Amplatz sheath is reintroduced directly into the bag. The nephroscope and lithotripter are inserted into the bag through the sheath and used to fragment the stone. Once the stone has been sufficiently fragmented, the bag can be pulled directly across the percutaneous tract. A suprapubic catheter is inserted into the bladder over the guidewire, which had been left in place traversing the percutaneous tract.

Postoperative Care and Complications

The Foley catheter is kept to drainage for approximately 1 week postsurgery to allow for adequate healing of the bladder closure. Output from the pelvic drain is monitored as high-output may indicate a urinary leak. If the output is low and there is adequate urine output from the Foley catheter, the drain may be removed, typically 48 hours after surgery. Drain fluid creatinine is not necessary unless high output is encountered. A cystogram should be performed before removal of the catheter to ensure that there is no extravasation present.

In cases of percutaneous cystolithotripsy in which a suprapubic tube has been placed, the tube may be clamped for between 24 and 48 hours following the procedure to allow for a trial of void. Once the patient has successfully voided, the suprapubic tube may be removed. If a urethral catheter is in place, it may be removed between 24 and 48 hours after the procedure to allow for a trial of void.

Key Points: Bladder Diverticulectomy

- The success of surgery is contingent on a meticulous preoperative workup that characterizes the number, size, and location of diverticula. Specifically, the anatomy relative to the ureter should be defined to ensure the preservation of ureteral integrity during repair.
- The disease process underlying formation of the bladder diverticulum should be managed before or at the time of diverticulum repair.
- The fibrous pseudocapsule surrounding the diverticulum serves as a cleavage plane to free the diverticulum from surrounding extravesical tissue.
- During minimally invasive bladder diverticulectomy, selective catheterization of the diverticulum with a Councill-tip catheter placed over a guidewire allows for selective filling of the diverticulum and aids in intraoperative identification.

Ureteral Reimplantation

- Avoid aggressive skeletonizing of the ureter during mobilization as this may lead to ischemia and ureteral stricture formation.
- A tension-free anastomosis between the bladder and ureter is critical because the presence of tension risks anastomotic stricture formation.
- The ureter should be adequately spatulated before creation of the anastomosis.
- When performing a nonrefluxing ureteral reimplant, the length of a submucosal tunnel should be three to five times the caliber of the ureteral lumen.
- Longer ureteral defects may be bridged through maneuvers such as ligation of the contralateral medial umbilical ligament, dissection of the peritoneal reflection off the bladder dome, or ligation of the contralateral bladder pedicle, all of which are conducive to cephalad displacement of the bladder.

Psoas Hitch and Boari Flap

- During creation of a psoas hitch, sutures that fix the extravesical surface of the bladder to the psoas minor tendon should be placed superficially and parallel to the direction of the muscle fibers to avoid entrapment of the femoral and genitofemoral nerves, respectively.
- Reimplantation of the ureter should be performed before tying the anchoring sutures to the psoas muscle tendon during psoas hitch creation.
- The base of a Boari flap should measure at least 4 cm in width, with longer flaps requiring wider base measurement to maintain adequate blood supply; in this regard, the length-to-base ratio should not exceed 3 : 1.
- If a nonrefluxing anastomosis is planned into a Boari flap, there should be at least 3 cm of overlap between the flap and the ureteral segment.
- Because of its relative simplicity and versality, advancement flaps may be used in lieu of Boari flaps to bridge longer ureteral defects.

Enterocystoplasty

- The ileum is most frequently utilized for bladder augmentation given its abundance, ease of mobilization, and robust blood supply.

- The ileum should be isolated approximately 20 cm proximal to the ileocecal valve to spare the terminal ileum and avoid risk for bile salt and vitamin B_{12} malabsorption.
- Detubularization of the isolated intestinal segment is necessary to reduce coordinated peristaltic contractions, which may otherwise contribute to high intravesical pressures.
- A broad mesenteric base to the isolated intestinal segment should be maintained to avoid torsion of the pedicle and preserve a rich blood supply.
- The bladder should be generously bivalved along its dome so as to facilitate a wide-mouth anastomosis with the intestinal patch; a narrow-mouth anastomosis would result in the creation of a pseudo-diverticulum that may poorly empty and cause complications.
- Patients should be counseled regarding the importance of continuous intermittent catheterization as the failure to do so risks perforation.

Partial Cystectomy and Urachal Surgery

- Preoperative evaluation should confirm the presence of adequate bladder capacity and the absence of significant voiding symptoms before proceeding with partial cystectomy.
- Partial cystectomy for benign disease processes still requires adequate margins of resection given the infiltrative nature of many conditions and the propensity for recurrence in cases of inadequate excision.
- During minimally invasive partial cystectomy, intraoperative flexible cystoscopy by the bedside assistant can aid the surgeon in identification of the site of bladder pathology.
- Urachal surgery, when being performed for benign indication, does not require a wide margin of resection of the bladder dome around the site of urachal insertion.

Bladder Stone Surgery

- Approach to bladder stone surgery depends on the size and number of calculi and the presence of any associated processes contributing to stone formation that may need to be simultaneously addressed.
- Percutaneous cystolithotripsy is a minimally invasive alternative to

management of large bladder calculi; percutaneous access, however, may be prohibited in patients with prior pelvic or abdominal surgery given concern over intestinal injury.

Genital and Lower Urinary Tract Trauma

Allen F. Morey MD, FACS, Jay Simhan MD, FACS

The lower urinary tract may sustain injury through a wide variety of mechanisms. Although rarely life-threatening, mismanagement of these injuries can lead to devastating long-term morbidity and, in some cases, permanent disability. The best outcomes can be achieved by employing appropriate imaging and identifying the optimal timing and approach for intervention.

In the acute setting, it is important to distinguish between scenarios when immediate reconstruction is appropriate, such as testicular rupture, and when reconstruction is best offered in the delayed setting, such as cases of pelvic fracture urethral injury. Appropriate management at the time of injury also facilitates delayed reconstruction, such as initial placement of a large-bore suprapubic tube for urethral injury followed by delayed posterior urethroplasty.

Improved technology and wider availability have made imaging more useful in lower urinary tract trauma, allowing for prompt and accurate diagnosis of injury. Better localization of the site of injury also allows the surgeon to select more direct or minimally invasive approaches for repair. Ultrasonography is routinely performed for scrotal trauma and is being performed more widely for confirming diagnosis of penile fracture. High-resolution computed tomography (CT) cystography can pinpoint the site of bladder rupture, facilitating diagnosis and making laparoscopic or robotic repair an excellent option. Retrograde urethrography can diagnose pelvic fracture urethral injury and differentiate between injuries in which primary realignment is feasible and those in which suprapubic tube placement is the better alternative.

Injuries of the External Genitalia

Penis

Traumatic injuries to the genitalia are uncommon, in part because of the mobility of the penis and scrotum. Blunt phallic traumatic injury is usually of concern only with an erect penis, when fracture of the tunica albuginea may result. In general, prompt surgical reconstruction of most penile injuries usually leads to adequate and acceptable cosmetic and functional results.

Fracture

Etiology.

Penile fracture is the disruption of the tunica albuginea with rupture of the corpus cavernosum. Fracture typically occurs during vigorous sexual intercourse, when the rigid penis slips out of the vagina and strikes the perineum or pubic bone, producing a buckling injury.

The tunica albuginea is a bilaminar structure (inner circular, outer longitudinal) composed of collagen and elastin. The outer layer determines the strength and thickness of the tunica, which varies in different locations along the shaft and is thinnest ventrolaterally (Brock et al., 1997; Hsu et al., 1994). When the erect penis bends abnormally, the abrupt increase in intracavernosal pressure exceeds the tensile strength of the tunica albuginea, and a transverse laceration of the proximal shaft usually results.

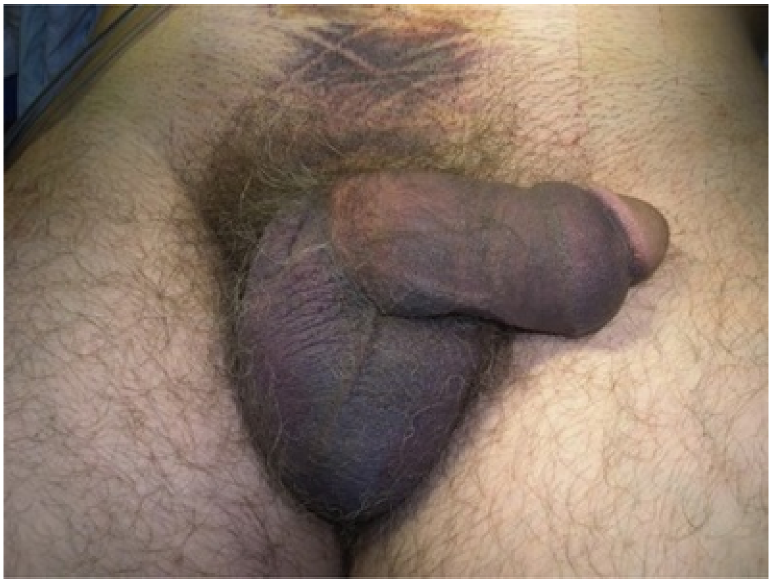
Although penile fracture has been reported most commonly with sexual intercourse with the “doggy style” position being the most common (Barros et al., 2017), it also has been described with masturbation, rolling over or falling onto the erect penis, and other scenarios (Al Ansari et al., 2013). Penile fracture may occur more frequently in “stressful situations” such as extramarital sex (Kramer, 2011). In the Middle East, self-inflicted fractures predominate resulting from the practice of “taqaandan,” in which the erect penis is forcibly bent during masturbation or as a means to achieve rapid detumescence after coitus (Zargooshi, 2009).

Cultural factors likely contribute to the varying etiologies of penile fracture. Mydlo (2001) reported that 94% of fractures in Philadelphia, Pennsylvania, were a result of sexual intercourse; Zargooshi (2009) described 76% of fractures in

Kermanshah, Iran, as being caused by self-manipulation. The tunical tear is usually transverse and 1 to 2 cm in length (Asgari et al., 1996; Mydlo, 2001). The injury is usually unilateral, although tears in both corporeal bodies occur in 10% of injuries (El-Taher et al., 2004; Mydlo, 2001). Bilateral corporeal injuries are more commonly associated with urethral injury (Koifman et al., 2010). **Although the site of rupture can occur anywhere along the penile shaft, fractures are most often distal to the suspensory ligament. Injuries associated with coitus are usually ventral or lateral** (Lee et al., 2007; Mydlo, 2001)**, where the tunica albuginea is the thinnest** (Hsu et al., 1994).

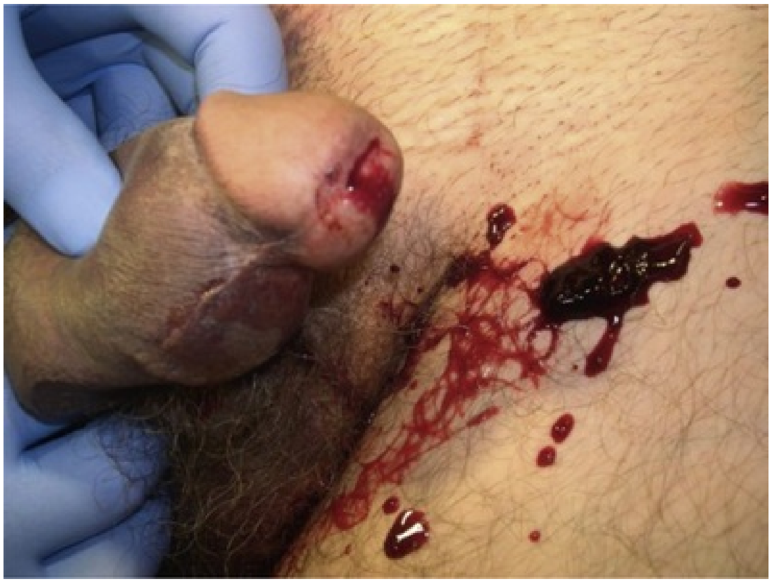
Diagnosis and Imaging.

The diagnosis of penile fracture is often straightforward and can be made reliably by history and physical examination. Patients usually describe a cracking or popping sound as the tunica tears, followed by pain, rapid detumescence, and discoloration and swelling of the penile shaft (American Urological Association [AUA] Urotrauma Guidelines, Statement 26). If Buck's fascia remains intact, the penile hematoma remains contained between the skin and tunica, resulting in a typical “eggplant deformity.” If Buck's fascia is disrupted, the hematoma can extend to the scrotum, perineum, and suprapubic regions (eFig. 133.1). The swollen, ecchymotic phallus often deviates to the side opposite the tunical tear because of the resultant hematoma and mass effect. The fracture line in the tunica albuginea may be palpable. Because fear and embarrassment are common, the patient's presentation to the emergency department or clinic is sometimes significantly delayed.



EFIG. 133.1 Eggplant deformity—the classic appearance of a penile fracture sustained during intercourse, with hematoma of the penile shaft and ecchymosis extending into the scrotum.

The incidence of urethral injury is significantly higher in the United States and Europe (20%) than in Asia, the Middle East, and the Mediterranean region (3%), probably because of the different etiology—intercourse trauma versus self-inflicted injury (Derouiche et al., 2008; Eke, 2002; Jack et al., 2004; Zargooshi, 2009). Most urethral injuries are associated with gross hematuria, blood at the meatus (eFig. 133.2), or inability to void, although the absence of these findings does not definitively rule out urethral injury (Jack et al., 2004; Koifman et al., 2010; Mydlo, 2001; Tsang and Demby, 1992). In cases that are suspicious of penile fracture with concomitant urethral injury, urethral evaluation is compulsory. **Given that urethral injury occurs frequently** (Pariser et al., 2015)**, preoperative urethrography can be considered when urethral injury is suspected. However, because urethrography can be time-consuming and inaccurate** (Kamdar et al., 2008)**, intraoperative flexible cystoscopy is now often performed routinely just before catheter placement at the time of penile exploration when urethral injury is suspected** (AUA Urotrauma Guidelines, Statement 29).



EFIG. 133.2 Blood at the urethral meatus noted in this patient with a penile fracture sustained during intercourse.

The typical history and clinical presentation of penile fracture usually make adjunctive imaging studies unnecessary. However, when the history and physical examination are equivocal for penile fracture, ultrasonography can establish the diagnosis (AUA Urotrauma Guidelines, Statement 28; Koifman et al., 2010). **Ultrasonography (Fig. 133.3) has become the preferred imaging study to evaluate for equivocal penile fracture because it is rapid, readily available, noninvasive, inexpensive, and accurate. Penile ultrasonography is most useful for ruling out fracture in patients with low clinical suspicion** or to identify the location of the tear, potentially guiding the choice of incision (El-Assmy et al., 2011).

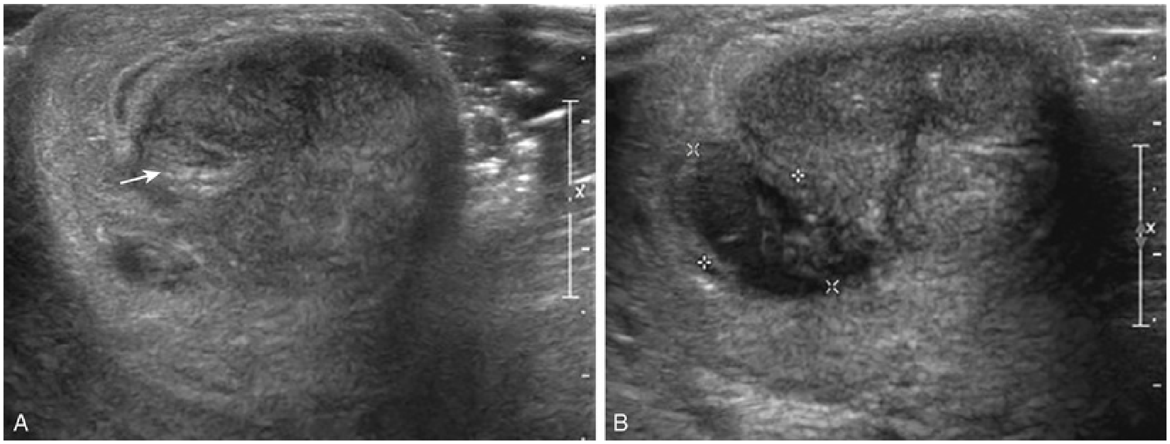


FIG. 133.3 (A) Ultrasound examination demonstrates ruptured tunica

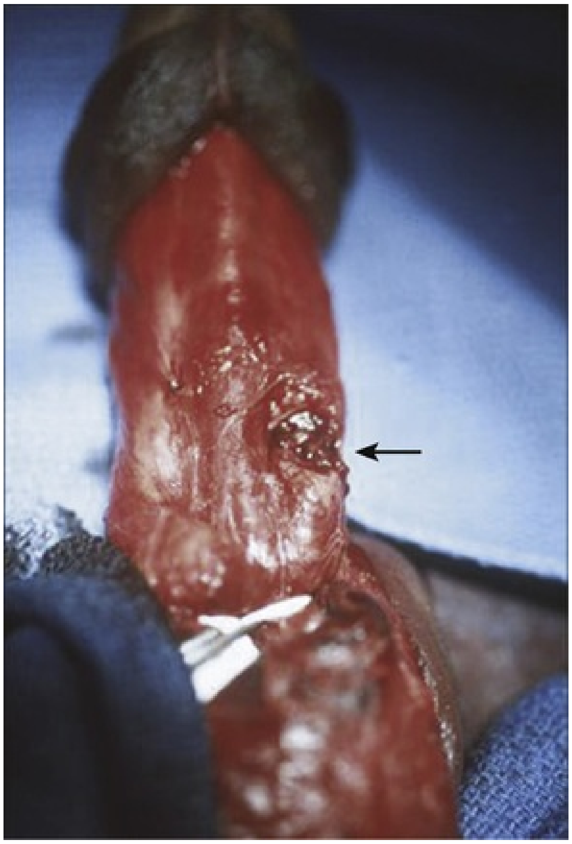
albuginea *(arrow)* in a patient with a suspected penile fracture. (B) Hematoma adjacent to ruptured tunica.

Magnetic resonance imaging (MRI) has been reported to be a noninvasive and accurate alternative means of demonstrating disruption of the tunica albuginea (Antonini et al., 2014; Fedel et al., 1996; Uder et al., 2002). However, because of the expense, limited availability, and time requirements involved, **MRI has not been employed widely for the evaluation of patients with symptoms and physical findings suggestive of penile fracture. AUA guidelines recommend MRI in the setting of equivocal ultrasound findings for penile fracture** (El-Assmy et al., 2011)**. Cavernosography is discouraged in the evaluation of a suspected penile fracture because it is time-consuming and unfamiliar to most urologists and radiologists** (Beysel et al., 2002; Morey et al., 2004).

False fracture has been reported in patients who present with penile swelling and ecchymosis, and some even describe the classic “snap-pop” or rapid detumescence typically associated with fracture (Feki et al., 2007). Physical examination may be inadequate for definitive diagnosis of a corporeal tear in these circumstances (Shah et al., 2003). Surgical exploration (eFig. 133.4) or evaluation with MRI should be considered (El-Assmy et al., 2010). Another condition that may mimic penile fracture is rupture of the dorsal penile artery or vein during sexual intercourse (Armenakas et al., 2001; Bar-Yosef et al., 2007).



EFIG. 133.4 Transverse laceration of left corpus cavernosum *(arrow)* associated with penile fracture, successfully repaired through a circumcision incision.

Management.

Multiple contemporary publications recommend that suspected penile fractures be promptly explored and surgically repaired (AUA Urotrauma Guidelines, Statement 27)**. Because most penile fractures occur ventrally or laterally, a ventral vertical penoscrotal incision is usually preferred for direct exposure to the fracture (Fig. 133.5)** (Mazaris et al., 2009)**. Alternatively, small lateral incisions may be used for localized hematomas or palpable tunical defects** (El-Bahnasawy and Gomha, 2000; Nasser and Mostafa, 2008)**. The distal circumcising incision may be appropriate when the location of the fracture is uncertain because it provides exposure to all three penile compartments. Closure of the tunical defect with interrupted 2-0 or 3-0 absorbable sutures is recommended; deep corporeal vascular ligation and excessive debridement of the delicate underlying erectile tissue should be avoided.**

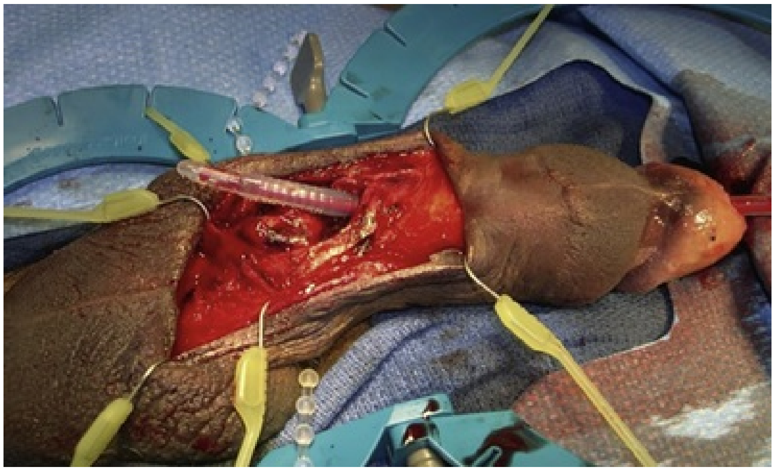


FIG. 133.5 Surgical exploration through a ventral vertical incision showing excellent exposure of the site of the tunical tear and associated urethral injury.

Induction of an artificial erection with saline or colored dye may aid in locating the corporal laceration (Shaeer, 2006). Partial urethral injuries should be oversewn with fine absorbable suture over a urethral catheter. Complete urethral injuries should be debrided, mobilized, and repaired in a tension-free manner over a catheter (Fig. 133.6). After urethral repair, the catheter is often maintained for 2 to 3 weeks while therapy with broad-spectrum antibiotics and 1 month of sexual abstinence are recommended. In uncircumcised patients, the distal circumcising incision may place the distal prepuce at risk for ischemia. Although a ventral vertical incision is preferred, if a distal circumcising incision is required, performing limited circumcision at the conclusion of the repair should be strongly considered.

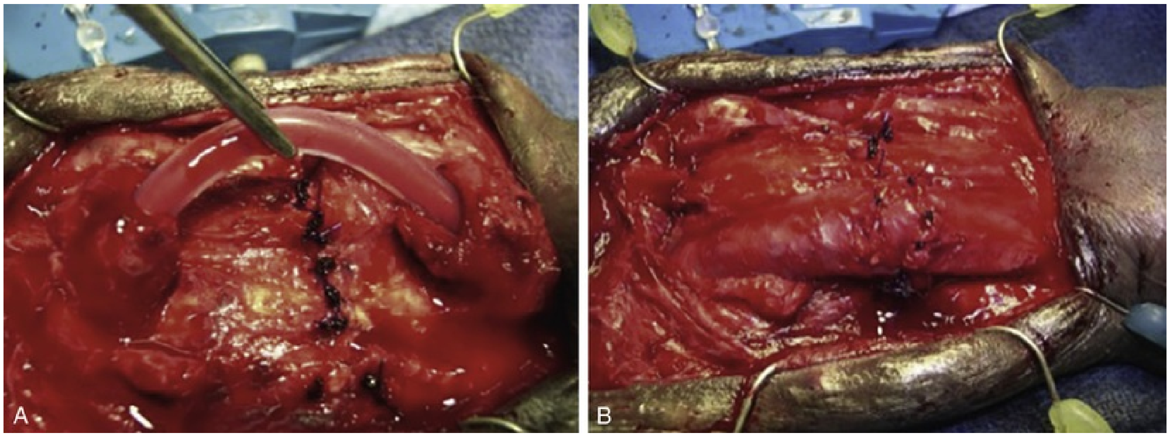

FIG. 133.6 (A) Completely transected urethra secondary to penile fracture. Repair of bilateral tunical rupture was performed previously. (B)

Anastomotic repair of the urethra after urethral mobilization.

Outcome and Complications.

Surgical reconstruction results in faster recovery, decreased morbidity, lower complication rates, and lower incidence of long-term penile curvature (AUA Urotrauma Guidelines, Statement 27; El-Taher et al., 2004; Hinev, 2002; Muentener et al., 2004; Nicolaisen et al., 1983; Orvis and McAninch, 1989). Although repair results in penile curvature in less than 5% of patients (El Atat et al., 2008), conservative management of penile fracture has been associated with penile curvature in more than 10% of patients, abscess or debilitating plaques in 25% to 30%, and significantly longer hospitalization times and recovery (Kalash and Young, 1984; Meares, 1971; Nicolaisen et al., 1983; Orvis and McAninch, 1989). Zargooshi (2009) reported in a surgical series of 352 patients that surgical management of penile fractures resulted in erectile function in nearly all patients. **Although surgery is better than conservative management, surgical delay of up to 7 days after the time of injury does not adversely affect the results of repair** (El-Assmy et al., 2011; Kozacioglu et al., 2011).

Gunshot and Penetrating Injuries

Gunshot Wounds.

Most penetrating wounds to the genitalia are caused by gunshots (Bjurlin et al., 2013; Mohr et al., 2003; Phonsombat et al., 2008), and most require surgical exploration. **Treatment principles include immediate exploration, copious irrigation, excision of foreign matter, antibiotic prophylaxis, and surgical closure.** Gunshot injuries to the phallus are rarely isolated wounds—nearly all victims have significant associated injuries, including abdominal, pelvic, lower extremity, vascular, or additional genitourinary injuries (Bandi and Santucci, 2004; Kunkle et al., 2008; Najibi et al., 2010). Excellent cosmetic and functional outcomes can be expected with immediate reconstruction (Cavalcanti et al., 2006; Gomez et al., 1993). An artificial erection may be induced to ensure penile straightness and no tunical violation, and plication techniques may be used to correct any curvature resulting from closure of a large corporal injury (Kunkle et al., 2008).

Urethral injuries have been reported in 15% to 50% of penile gunshot wounds (Cinman et al., 2013; Goldman et al., 1996; Miles et al., 1990; Mohr et al., 2003). **Retrograde urethrography should be strongly considered in any patient with penetrating injury to the penis, especially with high-velocity missile injuries, blood at the meatus, or difficulty voiding and when the trajectory of the bullet was near the urethra** (Bandi and Santucci, 2004; Cerwinka and Block, 2009; Goldman et al., 1996; Mohr et al., 2003; Phonsombat et al., 2008). Alternatively, intraoperative retrograde urethral injection of methylene blue or indigo carmine may identify the site of injury and the adequacy of closure. If a catheter has already been placed, pericatheter injection may help to ascertain urethral integrity.

Urethral injuries resulting from penetrating trauma should be closed primarily by use of standard urethroplasty principles whenever possible; excellent results have been reported (Bandi and Santucci, 2004; Miles et al., 1990). Patients with urethral injury and extensive tissue damage from high-velocity weapons or close-range shotgun blasts may require staged repair and suprapubic urinary diversion (Bandi and Santucci, 2004), especially injuries located in the penile urethra (Cavalcanti et al., 2006).

Animal and Human Bites.

The morbidity of animal bites is directly related to the severity of the initial wound. Most victims are boys, and dog bites are the most common injury (Gomes et al., 2001; Van der Horst et al., 2004). Infectious complications are unusual because treatment is sought early. **Initial management of dog bites includes copious irrigation, debridement, and immediate primary closure along with prophylactic use of a broad-spectrum antibiotic** (Bertozzi et al., 2009; Cummings and Boullier, 2000; Wolf et al., 1993). Tetanus and rabies immunizations should be used as appropriate. Because of the risk for polymicrobial infection and the antimicrobial susceptibilities of typical organisms, recommended empirical antimicrobial therapy choices include a β-lactam antibiotic with a β-lactamase inhibitor (i.e., amoxicillin-clavulanic acid), a second-generation cephalosporin with anaerobic efficacy (i.e., cefoxitin, cefotetan), or clindamycin with a fluoroquinolone (Talan et al., 1999).

Human bites produce contaminated wounds that often should not be closed primarily. Most individuals with human bite injuries seek medical attention after a substantial delay and are more likely to present with gross infection. Empirical antibiotic administration is warranted with amoxicillin/clavulanic acid or moxifloxacin (Talan et al., 2003).

Penile Amputation.

Traumatic amputation of the penis, although rare, is usually the result of genital self-mutilation. Psychosis is present in 65% to 87% of patients performing genital self-mutilation (Aboseif et al., 1993; Greilsheimer and Groves, 1979; Romilly and Isaac, 1996). Psychiatric consultation should be sought in all such cases.

Reconstruction of the urethra and reanastomosis of the corporeal bodies with microsurgical repair of dorsal penile vessels and nerves achieves remarkably good results. Patients should be transferred to a facility with microsurgical capabilities; however, if such a facility is unavailable, macroscopic anastomosis of the urethra and corporeal bodies can be performed with good erectile results, albeit with potential compromise of sensation and skin loss (Bhanganada et al., 1983; Razzaghi et al., 2009). Every attempt should be made to locate, clean, and preserve the severed portion in a "double bag" technique. The distal penis should be rinsed in saline solution, wrapped in saline-soaked gauze, and sealed in a sterile plastic bag, and the bag should be placed into an outer bag with ice or slush (AUA Urotrauma Guidelines, Statement 32; Jezior et al., 2001). **Hypothermic injury to the amputated segment can occur if it is in direct contact with ice for a prolonged period.** Successful reimplantation is possible after 16 hours of cold ischemia time or 6 hours of warm ischemia (Lowe et al., 1991). If the severed part is unavailable, the penile stump should be formalized by closing the corpora and spatulating the urethral neomeatus, similar to a partial penectomy procedure for malignant disease.

Microvascular reconstruction of the dorsal arteries, vein, and nerves is the preferred method of repair for an amputated penis. Adequate erectile function is possible with microvascular reanastomosis and macroscopic replantation, with more than 50% of men able to achieve erection with either technique (Aboseif et al., 1993; Bhanganada et al., 1983; Lowe et al., 1991; Morrison et al., 2017). However, **complications such as urethral strictures, skin loss, and sensory abnormalities all are less common with microvascular repair** (Jezior et al., 2001; Morrison et al., 2017).

Normal penile sensation returns in 0 to 10% of patients after macroscopic replantation (Bhanganada et al., 1983; Lowe et al., 1991), whereas sensation is present in more than 80% of patients with microscopic replantations (Jezior et al., 2001; Jordan and Gilbert, 1989; Lowe et al., 1991; Morrison et al., 2017). Penile skin necrosis, sometimes complete, is often a troublesome problem, although it is less common with microsurgical repair. This is because the blood supply of the skin is independent of the corporeal bodies and because without repair of the superficial vascular structures, the penile skin is essentially a free graft (Jezior et al., 2001). Split-thickness skin grafts are applied when the native skin becomes necrotic, usually after several weeks of observation, resuscitation, and debridement (Ozturk et al., 2009). An alternative strategy is to denude the phallus of all skin and bury it in the scrotum, leaving the glans exposed, followed by separation of the structures after 2 months (Bhanganada et al., 1983; Jordan and Gilbert, 1989). Adjuvant techniques after penile replantation include the use of hyperbaric oxygen to promote healing (Landström et al., 2004; Zhong et al., 2007) or medical leeches on the penis after macroreplantation to augment venous outflow and decrease edema (Mineo et al., 2004). Additionally, emerging techniques to manage total penile loss include utilization of radial artery–based forearm free flaps for total phallic reconstruction (Falcone et al., 2016).

Key Points: Step-by-Step Approach to Penile Reattachment

- Suprapubic cystostomy
- Closure of the tunica albuginea with 2-0 absorbable suture
- Urethral closure over a catheter with 4-0 absorbable suture
- Minimal dissection along the neurovascular bundle to identify severed vessels and nerves
- Microscopic anastomosis of dorsal artery with 11-0 nylon; microscopic dorsal vein repair with 9-0 nylon; microscopic epineural repair of dorsal nerve with 10-0 nylon
- Skin coverage

Zipper Injuries.

Zipper injuries to the penis more often happen to impatient boys or intoxicated men. Multiple maneuvers are available to free the entrapped skin and to remove the mechanism. After a penile block, the zipper slider and adjacent skin can be lubricated with mineral oil, followed by a single attempt to unzip and untangle the skin (Kanegaye and Schonfeld, 1993; Mydlo, 2000). The cloth material connected to the zipper can be incised with perpendicular cuts in between each zipper tooth to release the lateral support of the zipper, allowing the device to fall apart and release the trapped skin (Oosterlinck, 1981). A bone cutter or similar tool can be used to cut the median bar (diamond-shaped connection) of the slider. This maneuver allows separation of the upper and lower shields of the slider, and the entire zipper falls apart (Flowerdew et al., 1977; Saraf and Rabinowitz, 1982). Alternatively, a screwdriver may be placed between the upper and lower shields of the slider, and a twisting action separates the two shields from the median bar and unravels the zipper (Raveenthiran, 2007). Another technique involves cutting the anterior shield with a wire cutter (Maurice and Cherullo, 2013). Some children may require more than local anesthesia or sedation; circumcision or an elliptical skin excision can be performed in the operating room under anesthesia (Mydlo, 2000; Yip et al., 1989).

Strangulation Injuries.

Accidental injuries with thread, hair, or rubber bands occur in children, but child abuse must be considered in such cases. Any child with unexplained penile swelling, erythema, or difficulty voiding should be examined closely for a hidden strangulating hair or string. Adults may place objects around the shaft as a means of sexual pleasure or to prolong an erection. The constricting device can reduce blood flow, cause edema, and induce ischemia; gangrene and urethral injury may develop in delayed presentations. Emergent treatment requires decompression of the constricted penis to allow blood flow and micturition.

String, hair, and rubber bands should be incised promptly. Initial attempts to remove a solid constricting device causing penile strangulation involve lubrication of the shaft and foreign body and attempted direct removal. Edema distal to the strangulation often makes removal difficult. A string or latex tourniquet can be wrapped around the distal shaft to decrease swelling and to improve the odds of removing the device with lubrication. If the constricting object cannot be severed or removed, a string technique should be considered (Browning and Reed, 1969; Vahasarja et al., 1993; Noh et al., 2004). A thick silk suture or umbilical tape is passed proximally under the strangulation object and wound tightly around the penis distally toward the glans. The tag of suture or tape proximal to the ring is grasped; unwinding from the proximal end pushes the object distally. Glanular puncture with a needle or blade allows escape of dark trapped blood and improves the odds of removing the object with the string method (Browning and Reed, 1969; Noh et al., 2004).

Plastic constricting devices can be incised with a scalpel or an oscillating cast saw (Pannek and Martin, 2003), but metal objects present a more difficult challenge. Readily available hospital equipment (ring cutters, bolt cutters, dental drills, commercially available rotary tools, orthopedic and neurosurgical operative drills) may be inadequate to cut through heavy iron or steel items. The use of industrial drills, steel saws, hacksaws, saber saws, and high-speed electric drills is often required (Perabo et al., 2002; Santucci et al., 2004). Occasionally, fire department and emergency medical services equipment may be required to cut through iron and steel rings. The phallus should be protected from thermal injury, sparks, and the cutting blade by use of tongue depressors, sponges, or malleable retractors; continuous saline irrigation may be used for cooling (Video 133.1). Such elaborate undertakings are best accomplished in the operating room under anesthesia. If decompression is delayed and the patient is distended and unable to void, a suprapubic bladder catheter should be placed. Outcomes are generally favorable with device removal alone, although the surgeon should be prepared to consider reconstructive techniques such as skin grafting if the strangulation injury causes skin necrosis (Gaspar et al., 2015; Ivanovski et al., 2007).

Testis

Etiology

Although the testis is relatively protected by the mobility of the scrotum, reflexive cremasteric muscle contraction, and the tough fibrous tunica albuginea, blunt injury (usually the result of assault, sports-related events, and motor vehicle accidents) can result in rupture of the tunica albuginea, contusion, hematoma, dislocation, or torsion of the testis. Testicular injury results from blunt trauma in about 75% of cases (Cass and Luxenberg, 1991; McAninch et al., 1984), whereas penetrating injuries secondary to firearms, explosions, or impalement account for the remaining cases.

Although only 1.5% of blunt testis injury involves both gonads, about 30% of penetrating scrotal trauma results in bilateral injury (Cass and Luxenberg, 1988, 1991). Similar to penetrating urethral injuries, penetrating scrotal trauma (roughly 80%) usually involves neighboring structures, including the thigh, penis, perineum, bladder, urethra, or femoral vessels (Cline et al., 1998; Gomez et al., 1993; Simhan et al., 2012). In contemporary military conflicts, genital wounds account for a larger percentage of urologic injuries because of the powerful explosive weapons involved and absence of protective body armor over the genitalia (Janak et al., 2017; Thompson et al., 1998; Waxman et al., 2009). Blast injuries are typically associated with extensive scrotal skin loss, multiple projectile injuries of both testes, and concomitant extensive destruction of the lower extremities and abdomen.

Diagnosis

Rupture of the testis must be considered in all cases of blunt scrotal trauma. Most patients complain of exquisite scrotal pain and nausea. **Swelling and ecchymosis are variable, and the degree of hematoma may not correlate with the severity of testicular injury; absence does not entirely rule out testicular rupture, and contusion without fracture can manifest as significant bleeding.** Scrotal hemorrhage and hematocele along with tenderness to palpation often limit a complete physical examination. Concomitant urethral injury should be suspected and evaluated when examination reveals blood at the meatus or if the mechanism of injury or hematuria suggests this possibility. Penetrating injuries mandate careful examination of surrounding structures, especially the femoral vessels.

Ultrasonography can be helpful to assess the integrity and vascularity of the testis in equivocal cases. Ultrasonography is rapid, readily available, and noninvasive. Because it may be operator dependent, false-positive and false-negative studies range from 56% to 94% (Corrales et al., 1993; Dreitlein et al., 2001; Fournier et al., 1989; Herbener, 1996). **Ultrasound findings suggestive of testicular fracture include a heterogeneous echo pattern of the testicular parenchyma and disruption of the tunica albuginea (Fig. 133.7)** (Bjurlin et al., 2013; Buckley and McAninch, 2006; Micallef et al., 2001)**. Although ultrasonography may assist in detection of testicular fracture or hematoma** (Guichard et al., 2008)**, a normal or equivocal ultrasound study should not delay surgical exploration when physical examination findings suggest testicular damage; definitive diagnosis is often made in the operating room** (AUA Urotrauma Guidelines, Statement 30). Although MRI may effectively demonstrate testicular integrity, its widespread use is not the norm because of expense, limited availability, and potential delay in definitive surgical care of the patient (Kim et al., 2009; Muglia et al., 2002; Serra et al., 1998).

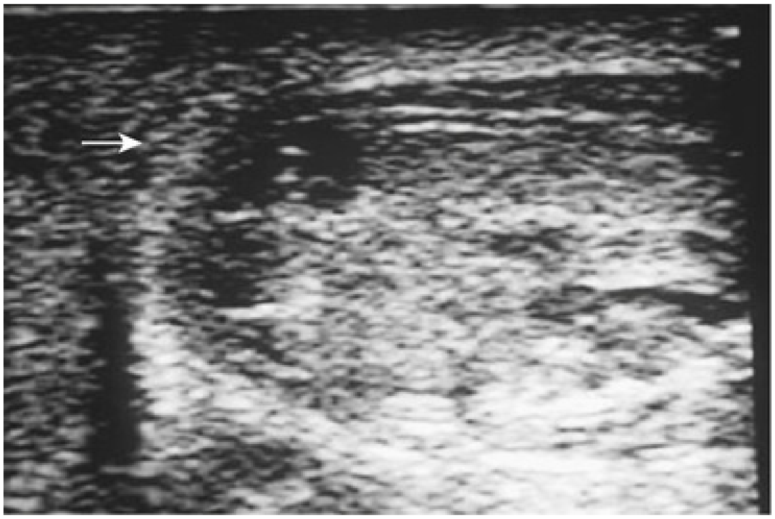

FIG. 133.7 Ultrasound examination demonstrates hypoechoic intratesticular areas *(arrow)* consistent with testicular rupture sustained by blunt trauma. Scrotal exploration revealed a large hematocele and exposed seminiferous tubules.

Differential diagnosis of testicular fracture includes hematocele without rupture, torsion of the testis or an appendage, reactive hydrocele, hematoma of the epididymis or spermatic cord, and intratesticular hematoma. A nonpalpable testis in a trauma patient should raise the possibility of dislocation outside the scrotum. This entity usually occurs after motorcycle crashes when extreme forces on the scrotum expel the testis into surrounding tissues such as the superficial inguinal pouch (50%) or to a pubic, penile, pelvic, abdominal, or perineal location (Bromberg et al., 2003; Schwartz and Faerber, 1994). Bilateral dislocation after trauma has been reported (Bromberg et al., 2003; O'Brien et al., 2004). Manual or surgical reduction of the displaced testis is indicated. Finally, approximately 5% of spermatic cord torsions are thought to be precipitated by trauma; torsion should be considered in all cases of significant scrotal pain without signs or symptoms of major scrotal trauma (Elsaharty et al., 1984; Lrhorfi et al., 2002; Manson, 1989).

Management

Early exploration and repair of testicular injury is associated with increased testicular salvage, reduced convalescence and disability, faster return to normal activities, and preservation of fertility and hormonal function (Kukadia et al., 1996). Minor scrotal injuries without testicular damage can be managed with ice, elevation, analgesics, and irrigation and closure in some circumstances.

The objectives of surgical exploration and repair are testicular salvage, prevention of infection, control of bleeding, and reduced convalescence. Either transverse or vertical scrotal incisions can be performed for successful exploration. **The tunica albuginea should be closed with small absorbable sutures after removal of necrotic and extruded seminiferous tubules.** Even small defects in the tunica albuginea should be closed primarily because progressive swelling and any rise in intratesticular pressure can continue to extrude seminiferous tubules over time. Every attempt to salvage the testis should be performed. Loss of capsule tissue may require removal of additional parenchyma to allow closure of the remaining tunica albuginea. A flap or graft of tunica vaginalis may be used to cover a large defect in the tunica albuginea in an otherwise salvageable testis (Fig. 133.8); synthetic grafts are not recommended for this purpose (Ferguson and Brandes, 2007). Significant intratesticular hematomas should be explored and drained, even in the absence of testicular rupture to prevent progressive pressure necrosis and atrophy, delayed exploration (40%), and orchiectomy (15%) (Cass and Luxenberg, 1988). Significant hematoceles should also be explored, regardless of imaging studies, because up to 80% are caused by testicular rupture (Buckley and McAninch, 2006; Vaccaro et al., 1986).

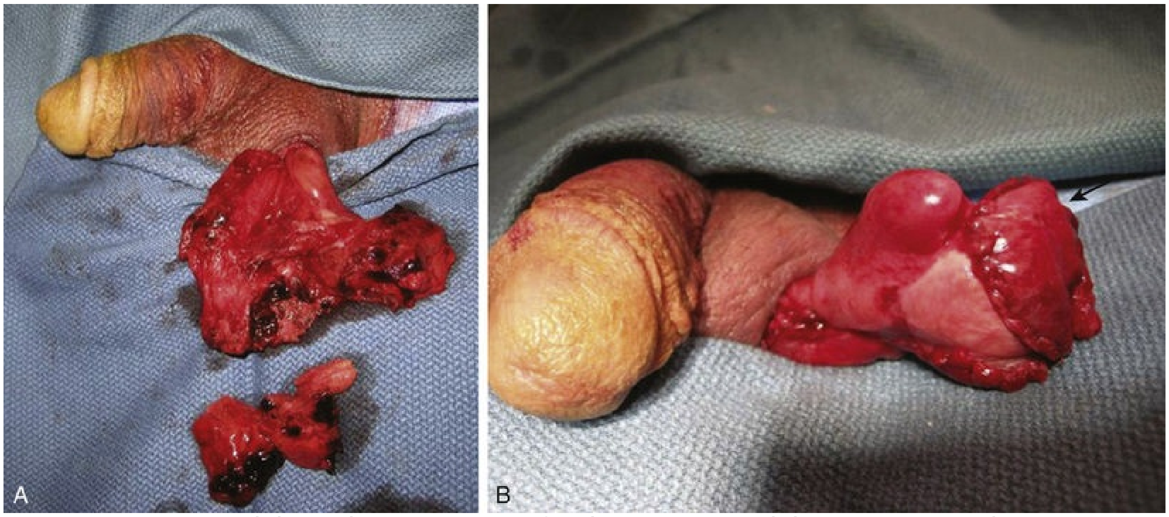

FIG. 133.8 (A) Testicular rupture after blunt trauma. (B) Reconstructed testis after debridement and closure. *Arrow* indicates placement of a tunica vaginalis graft.

Penetrating scrotal injuries should be surgically explored to inspect for vascular and vasal injury; the same principles of salvage, hemostasis, and reconstruction apply as in blunt trauma. The vas deferens is injured in 7% to 9% of scrotal gunshot wounds (Brandes et al., 1995; Gomez et al., 1993). The injured vas should be ligated with nonabsorbable suture, and delayed reconstruction should be performed if necessary. Depending on the mechanism and trajectory of the projectile, scrotal exploration of the contralateral testis should be considered (Simhan et al., 2012).

Outcome and Complications

Nonoperative management of testicular rupture is frequently complicated by infection, atrophy, necrosis, chronic unrelenting pain, and delayed orchiectomy. **Testicular salvage rates exceed 90% with exploration and repair within 3 days of injury** (Cass and Luxenberg, 1991; Del Villar et al., 1973; Fournier et al., 1989; Schuster, 1982)**, whereas orchiectomy rates are threefold to eightfold higher with conservative management and delayed surgery** (Cass and Luxenberg, 1991). Indicative of the benefits of early intervention, testicular salvage rates with conservative management approach only 33%, with delayed orchiectomy rates between 21% and 55% (Cass and Luxenberg, 1991; McAleer and Kaplan, 1995; Schuster, 1982). Timely surgical intervention for testis injury is also probably warranted as roughly one-half of patients initially managed conservatively fail and will ultimately undergo surgical exploration for pain, infection, and persistent hematoma (Cass and Luxenberg, 1991; Del Villar et al., 1973). Convalescence and time of return to normal activities are significantly reduced after early surgical repair.

In contrast with blunt testis rupture, for which salvage rates are very high, penetrating testicular trauma has historically been associated with gonad salvage in only 32% to 65% of cases in historic cohorts (Bickel et al., 1990; Brandes et al., 1995; Cline et al., 1998; Gomez et al., 1993). However, likely secondary to heightened provider awareness, improved salvage rates as high as 86% have been reported in more recent civilian series (Bjurlin et al., 2013; Phonsombat et al., 2008; Simhan et al., 2012) and combat series (Al-Azzawi et al., 2014; Janak et al., 2017; Waxman et al., 2009). Most surgical patients have adequate preservation of hormonal and fertility function (Kukadia et al., 1996). Sperm production has been documented in men with appropriately repaired bilateral testis rupture and bilateral penetrating injuries (Brandes et al., 1995; Pohl et al., 1968).

Urologists may be consulted for opinion and guidance with regard to boys with a solitary testis who play a contact sport. Testicular injuries are exceedingly rare in boys involved in individual or team contact sports and recreational activities (McAleer et al., 2002; Wan et al., 2003a, 2003b). Parents should be appropriately counseled, and a protective cup device should be recommended, but it also must be made clear that the benefits of continued physical activity far outweigh any concerns for potential complications (Diokno and Rowe, 2010). Further, the American Academy of Pediatrics Committee on Sports Medicine and Fitness has definitively recommended that children with a solitary testicle be allowed to participate universally in noncontact and full-contact sports (Rice, et al., 2008).

Genital Skin Loss

Etiology

Necrotizing gangrene secondary to polymicrobial infection in the genital area, or Fournier gangrene, is the most common cause of extensive genital skin loss (McAninch et al., 1984). Skin loss is iatrogenic, caused by the necessity for acute debridement of necrotic genital skin and optimization of infection control.

Penile skin loss can result from traction by mechanical devices, such as farm or industrial machinery, or by suction devices, such as vacuum cleaners. Because the superficial penile tissue is loose areolar tissue, it is often torn free without damage to the underlying structures. Significant scrotal skin loss resulting from penetrating trauma is uncommon, but it can be seen more commonly in explosive injuries (Fig. 133.9) (Janak et al., 2017).

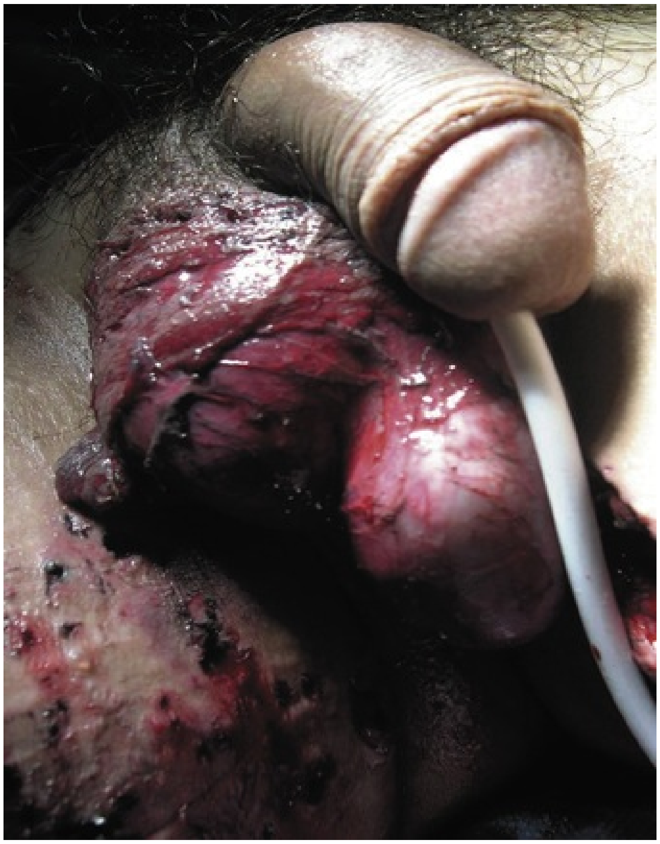

FIG. 133.9 Extensive loss of scrotal skin from explosive blast injury. Note numerous concomitant shrapnel injuries to the thigh.

Penile burns, although rare, are often full-thickness burns because the penile skin is so thin (Horton and Dean, 1990). Constricting bands placed on the penis can result in significant skin loss, although a more common injury involves direct pressure necrosis under the band, which usually heals well with device removal alone.

Diagnosis and Initial Management

Although both cellulitis and Fournier gangrene are commonly associated with significant genital edema and erythema, skin ischemia with crepitus is the hallmark of Fournier gangrene. The finding of loss of scrotal rugae is highly suggestive of tissue necrosis. Scrotal ultrasonography (Kane et al., 1996; Morrison et al., 2005) and CT may reveal subcutaneous air, a helpful indicator of necrotizing infection (Fig. 133.10).

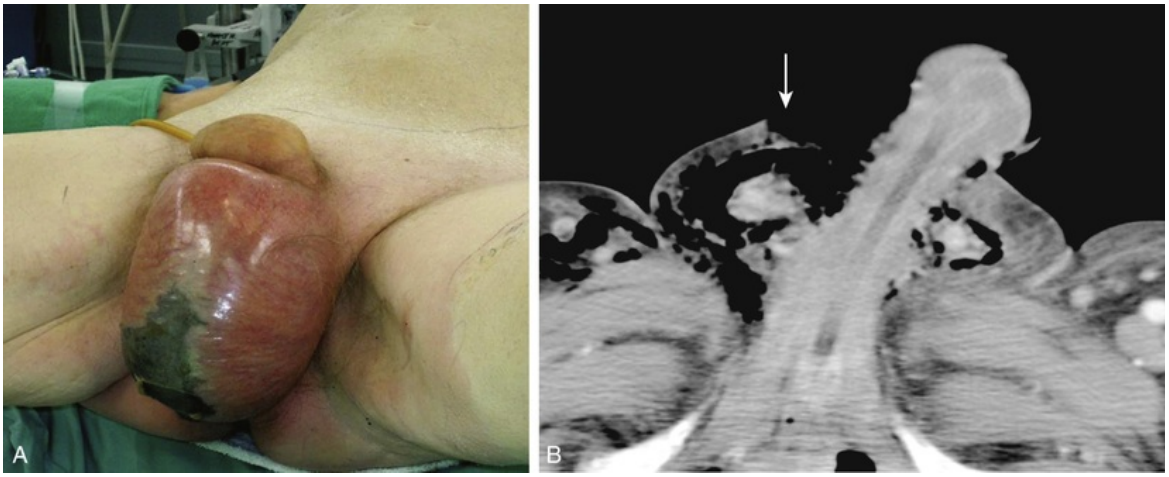

FIG. 133.10 (A) Large erythematous scrotum with central necrosis suggestive of necrotizing infection. (B) Computed tomography scan reveals subcutaneous air in the scrotum *(arrow)* secondary to Fournier gangrene.

In most cases of Fournier gangrene, multiple debridements of ischemic or frankly necrotic skin are required over a period of several days until active infection is controlled (AUA Urotrauma Guidelines, Statement 31). Wounds are treated with frequent wet-to-dry dressing changes or with vacuum-assisted closure therapy (Czymek et al., 2009) until primary coverage is planned. Inspection at least daily by the surgical team is mandatory. **Early suprapubic urinary diversion should be strongly considered for extensive injuries to simplify wound care and to prevent urethral complications related to prolonged catheterization.** Hyperbaric oxygen treatment has been advocated as an adjunctive measure to promote wound healing, although we do not recommend this because of the considerable increased expense and logistical complexity in the absence of proven benefit (Mindrup et al., 2005). Negative-pressure wound care therapy can also be utilized in complex cases of Fournier gangrene with large wound surface areas to reduce mortality and theoretically promote wound granulation (Czymek et al., 2009).

Genital burns are largely treated similarly to other burns, with early resection of burn eschar and coverage with split-thickness skin grafts when possible. Partial-thickness skin loss or genital burns may be treated with silver sulfadiazine cream. For deep penile electrical burns, a conservative approach is warranted because the ultimate outcome usually is autopenectomy and/or death as a result of extensive concurrent injuries (Medendorp et al., 2007).

Penile Reconstruction

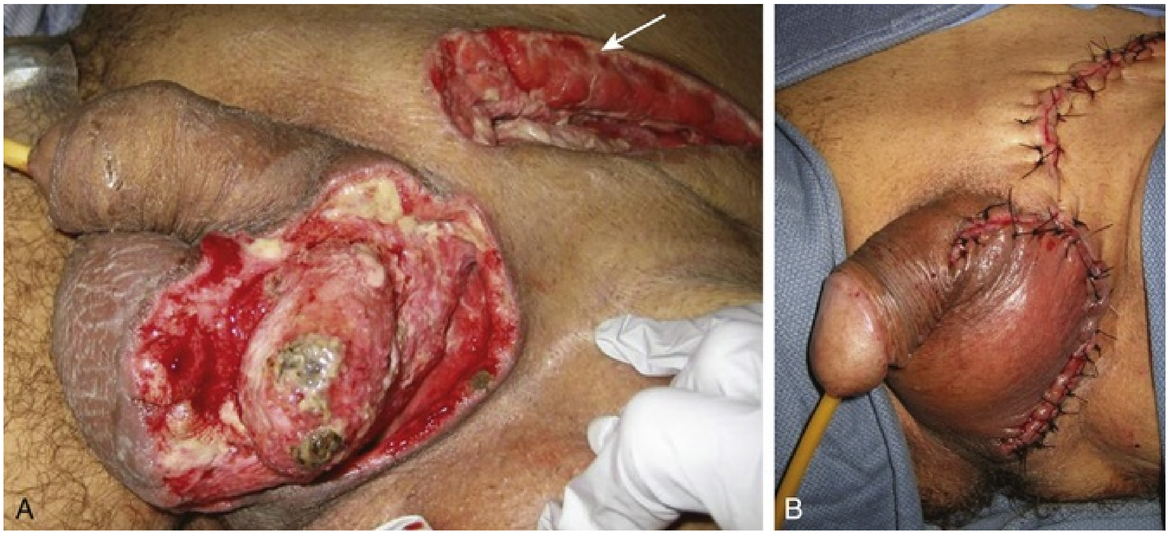
In selected uncircumcised patients, mobilization of redundant foreskin may allow primary closure of middle to distal penile skin loss (Horton and Dean, 1990). Scrotal rotation flaps can also be used for more proximal defects if skin loss is limited, but the hair-bearing nature of scrotal skin risks an unacceptable cosmetic result (Zhao et al., 2009). Local flaps, such as from the abdomen and thigh, can be used but are cosmetically inferior to split-thickness skin grafts. Skin coverage with avulsed skin should be avoided because it often becomes necrotic.

Thick (0.012- to 0.015-inch), nonmeshed, split-thickness skin grafts (McAninch et al., 1984) **are preferred for penile reconstruction.** Meshed grafts can be used but have a tendency to contract and are cosmetically inferior to unmeshed grafts. Grafts are usually harvested from the anterior thigh with a pneumatic dermatome. **If grafts are to be used, care must be taken to remove any subcoronal skin remaining after debridement. Lymphatic obstruction of this distal foreskin, if it is not excised, results in circumferential lymphedema** (McDougal, 2003). Graft stabilization in the immediate postoperative period may be achieved with either a tie-over-bolster technique or with a circumferential vacuum dressing (Senchenkov et al., 2006; Weinfeld et al., 2005). Skin grafts placed on the penile shaft never regain normal sensation (Horton and Dean, 1990), although sexual function is often preserved because of intact sensation in the glans and maintenance of corporal anatomy without alteration of blood flow.

Scrotal Reconstruction

Scrotal skin loss defects of up to 50% can often be closed directly. For extensive injuries, the testes may be placed in thigh pouches, treated with wet dressings, or placed under vacuum pressure dressings until reconstruction (Cuccia et al., 2009; Cummings and Boullier, 2000; Gomes et al., 2001). **Utilization of thigh pouches is often a historic maneuver that is not recommended initially because transmission of the infectious process into uninvolved tissues may occur.** During scrotal reconstruction, local skin flaps should be mobilized initially to cover as much of the tissue defect as possible (eFig. 133.11). Meshed split-thickness skin grafts can be employed for remaining reconstruction. In addition to providing an excellent cosmetic result, meshing allows exudate to escape from the interstices, improving graft take. The spermatic cords and testes are sewn together in multiple areas before grafting to prevent a bifid neoscrotum

(Tan et al., 2011). The neoscrotum may appear unnaturally tight initially, but after 6 to 12 months the testes eventually occupy a more natural dependent position. Thigh flaps can be used to reconstruct the scrotum when the testes have been buried in the thighs after traumatic or surgical scrotal removal (Morey and McAninch, 1999). Fibrin sealant has proven useful as a tissue glue to promote healing and to reduce drainage during complex genital reconstruction cases (Morris et al., 2006).



EFIG. 133.11 (A) Scrotal defect before final debridement and closure of left hemiscrotum for Fournier gangrene. *Arrow* indicates an inguinal counterincision made because of extension of infection to the inguinal canal. (B) Delayed primary closure. The right testis and tunica vaginalis were mobilized off the overlying scrotal tissue, which was then used to close the scrotal defect.

Key Points: Genital Trauma

- Although penile fracture can be diagnosed based on history and physical examination, penile ultrasonography is readily available, inexpensive, and rapid in equivocal cases.
- Gunshot wounds to the penis should be repaired primarily to prevent deformity and erectile dysfunction.
- Animal bites should be irrigated, debrided, and closed primarily, whereas most human bites should be left open.

- Blunt scrotal injury can be evaluated by ultrasonography for testicular rupture.
- Penetrating scrotal injuries should undergo surgical exploration to assess and repair deep tissues and remove contamination.

Bladder Injury

Etiology

The urinary bladder is generally protected from external trauma because of its deep location in the bony pelvis. Most blunt bladder injuries are the result of rapid-deceleration motor vehicle collisions, but many also occur with falls, crush injuries, assault, and blows to the lower abdomen. Disruption of the bony pelvis tends to tear the bladder at its fascial attachments, but bone fragments also can directly lacerate the organ. Other important causes of bladder rupture include penetrating trauma, iatrogenic surgical complications, and spontaneous rupture in patients with a history of neuropathic disease, preexisting bladder disease, or prior urologic surgery.

Bladder injuries that occur with blunt external trauma are rarely isolated injuries—80% to 94% of patients have significant associated nonurologic injuries (Bjurlin et al., 2009; Cass, 1984; Hsieh et al., 2002; Parry et al., 2003; Volpe et al., 1999). Mortality in these patients with multiple injuries is usually related to nonurologic injuries and ranges from 8% to 44% (Alli et al., 2003; Carroll and McAninch, 1984; Cass and Luxenberg, 1987; Corriere and Sandler, 1989; Parry et al., 2003; Volpe et al., 1999). **The most common associated injury is pelvic fracture, which is associated with 83% to 95% of bladder injuries** (Cass, 1989; Corriere and Sandler, 1989; Morey et al., 2001; Parry et al., 2003). Conversely, bladder injury has been reported to occur in only 5% to 10% of pelvic fractures (Aihara et al., 2002; Cass, 1989; Peters, 1989). Sudden force applied to a full bladder may result in a rapid increase in intravesical pressures and lead to rupture without pelvic fracture.

Penetrating bladder trauma is also associated with significant nonurologic injuries and mortality rate. Nearly one-half of all bladder injuries are iatrogenic (Dobrowolski et al., 2002); **obstetric and gynecologic complications are the most common causes of bladder injuries during open surgery** (Dobrowolski et al., 2002; Gomez et al., 2004).

Diagnosis and Radiographic Imaging

Extraperitoneal bladder injury is usually associated with pelvic fracture. Intraperitoneal injuries can be associated with pelvic fracture but are more commonly caused by penetrating injuries or burst injuries at the dome by direct blow to a full bladder. Appropriate diagnostic imaging is important because of the marked influence on management.

After blunt external trauma, the absolute indication for immediate cystography is gross hematuria associated with pelvic fracture; approximately 29% of patients presenting with this combination of findings have bladder rupture (AUA Urotrauma Guidelines, Statement 14; Morey et al., 2001). Relative indications for cystography after blunt trauma include gross hematuria without pelvic fracture and microhematuria with pelvic fracture. **The diagnosis of bladder rupture is extremely low in these atypical groups (e.g., 0.6% in patients with pelvic fracture and microhematuria), but the index of suspicion should be raised by associated clinical indicators of bladder injury. Conversely, penetrating injuries of the buttock, pelvis, or lower abdomen with *any* degree of hematuria warrant cystography.**

Key Points: Clinical Indicators of Bladder Injury

- Suprapubic pain or tenderness
- Free intraperitoneal fluid on CT or ultrasound examination
- Inability to void or low urine output
- Clots in urine or clots noted in bladder on CT
- Enlarged scrotum with ecchymosis
- Abdominal distention or ileus

Retrograde or stress cystography is nearly 100% accurate for bladder injury if performed appropriately. The bladder should be filled in cooperative and conscious patients to a sense of discomfort and otherwise to 350 mL. For a plain film technique, three images are obtained: one before administration of a contrast agent, one full-bladder anteroposterior film, and one drainage film. Posterior extravasation of the contrast medium can be missed without a drainage film. Significant bladder distention is required to visualize small tears. False-negative studies have been reported with retrograde instillation of only 250 mL (Morey and Carroll, 1997; Peters, 1989). Although hematuria and mechanism of injury mandate consideration of upper tract imaging studies, upper and lower urinary tract injuries are almost never coincident (0.4%) (Cass and Luxenberg,

1990).

A dense, flame-shaped collection of contrast material in the pelvis is characteristic of extraperitoneal extravasation (Fig. 133.12). Depending on fascial integrity, contrast material may extend beyond the confines of the pelvis and be visualized in the retroperitoneum, scrotum, phallus, thigh, or abdominal wall. The amount of extravasation is not always proportional to the extent of bladder injury. **Intraperitoneal extravasation is identified when contrast material outlines loops of bowel and/or the lower lateral portion of the peritoneal cavity.**

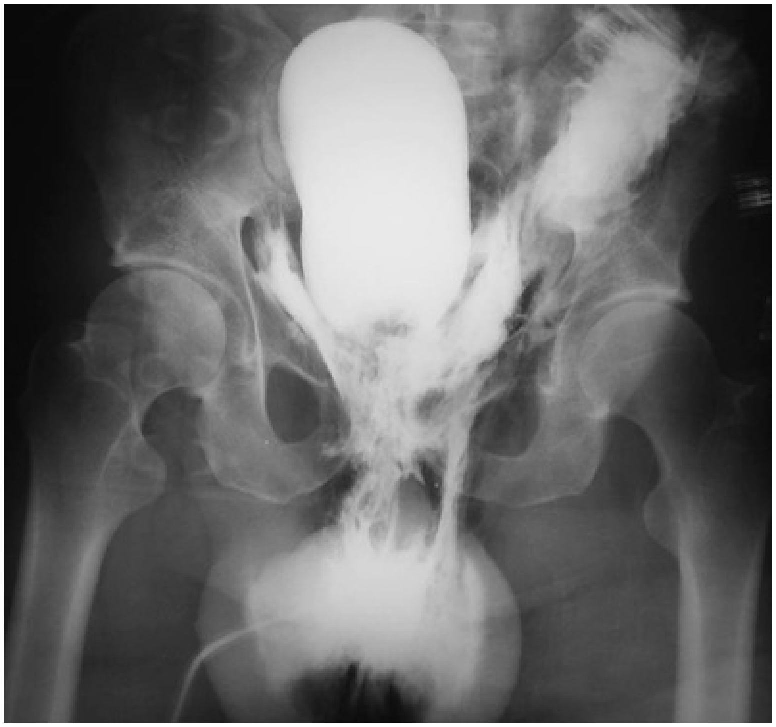


FIG. 133.12 Plain film cystogram reveals extraperitoneal bladder rupture with extravasation into the scrotum. Surgical exploration revealed anterior bladder neck and prostatic urethral laceration.

Because CT is now routinely used to assess trauma patients, concomitant CT cystography is frequently selected as a more efficient means to assess the bladder. CT cystography is as accurate and reliable as plain film cystography in evaluation of suspected bladder injury (Fig. 133.13), as long as the bladder is filled in retrograde fashion with contrast material diluted to 2% to 4% (6 : 1 dilution with saline) to a volume of 350 mL (Hsieh et al., 2002; Peng et al., 1999). Drainage films are not required after CT cystography because the retrovesical space can be well visualized with axial images (Morey and Carroll, 1997). Dilution of the contrast material is mandatory because undiluted contrast material is so dense that the CT quality is compromised by scatter artifact. **Clamping the urethral catheter in an attempt to allow antegrade distention of the bladder by intravenous contrast medium is notoriously inadequate for diagnosis of bladder rupture; retrograde filling is mandatory.** Conventional abdominal CT of a trauma patient may show findings suggestive of bladder injury, but it is not considered to be adequate for bladder evaluation without retrograde contrast distention (Hsieh et al., 2002; Mee et al., 1987; Udekwu et al., 1996).

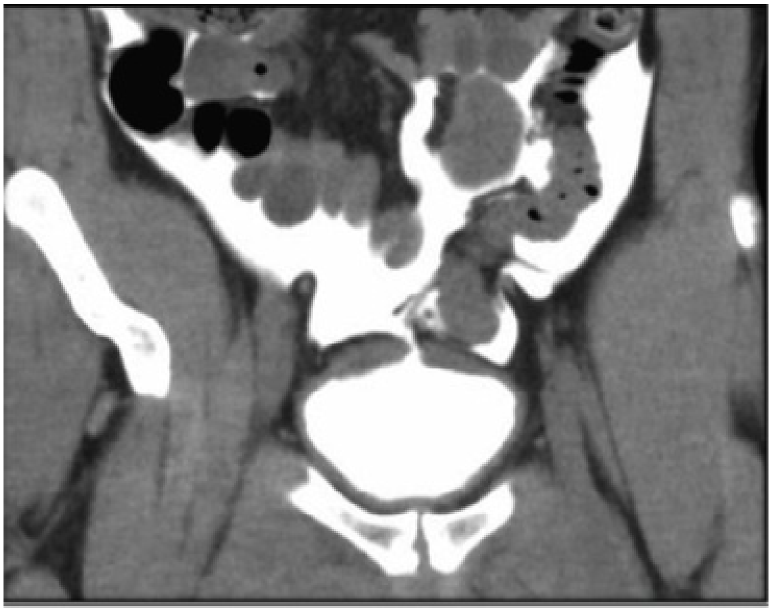

FIG. 133.13 Computed tomography cystogram demonstrates contrast material surrounding loops of bowel consistent with intraperitoneal bladder rupture.

Clinical Signs and Symptoms

Bladder rupture does not occur as an isolated, asymptomatic event in normal individuals. Conscious patients present with pronounced nonspecific symptoms such as suprapubic pain combined with the inability to void. Physical signs include suprapubic tenderness, lower abdominal bruising, muscle guarding and rigidity, and diminished bowel sounds. Associated abdominal and pelvic injuries may mask bladder symptoms. Higher suspicion for bladder injury is similarly warranted in patients who are unresponsive because of intoxication or altered sensorium.

Immediate catheterization should be performed when blunt bladder rupture is suspected. **The most reliable indicator is gross hematuria, which is present in nearly all cases** (Gomez et al., 2004; Hsieh et al., 2002; Iverson and Morey, 2001; Parry et al., 2003)**. If blood is noted at the meatus or the catheter does not pass easily, retrograde urethrography should be performed first because urethral injuries occur concomitantly in 10% to 29% of patients with bladder rupture** (Cass, 1989; Dobrowolski et al., 2002).

Management

The usual treatment of uncomplicated extraperitoneal bladder ruptures, when conditions are ideal, is conservative management with urethral catheter drainage alone (Fig. 133.14) (AUA Urotrauma Guidelines, Statement 16). A large-bore (22-Fr) Foley catheter should be used to promote adequate drainage; if output is poor, fluoroscopic cystography should be considered to ensure proper catheter placement. Cystography is necessary to verify complete healing before catheter removal 14 days after injury. If extravasation persists, continuation of urethral catheter drainage is maintained for several weeks, after which radiographic confirmation of healing is essential. Bone spicules within the bladder wall (eFig. 133.15) may compromise healing and thus prompt open repair. Antimicrobial agents are instituted on the day of injury and continued for at least 1 week to prevent infection of the pelvic hematoma.

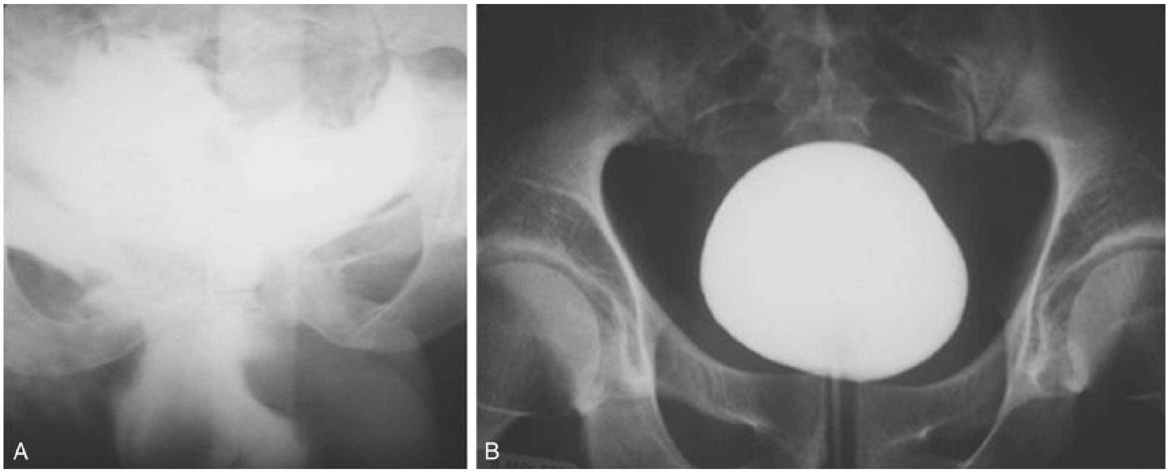

FIG. 133.14 (A) Dense flame-shaped pattern of contrast extravasation in the pelvis secondary to extraperitoneal bladder rupture. (B) Repeat

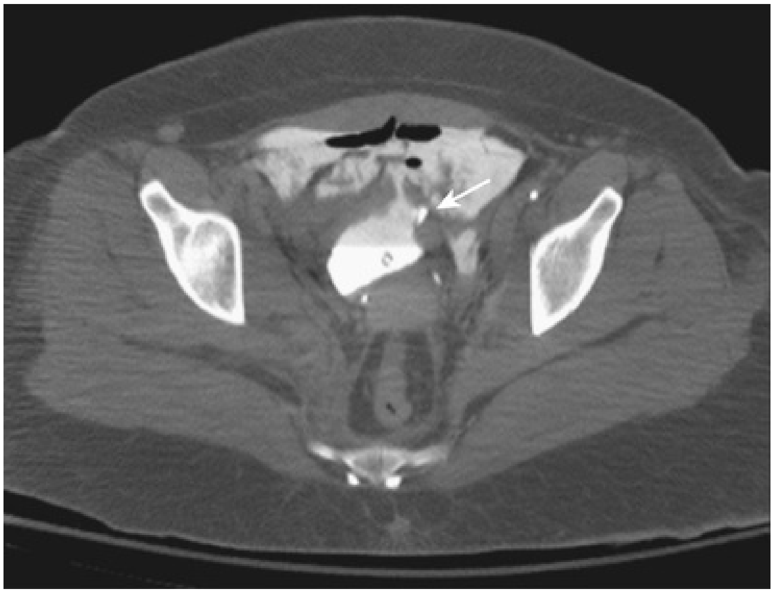
cystogram in the same patient after 2 weeks of catheter drainage shows a completely healed bladder.



EFIG. 133.15 Computed tomography cystogram of a patient with extraperitoneal bladder rupture after a motor vehicle/pedestrian collision and extensive pelvic fracture. *Arrow* indicates a fragment of bone in the bladder, removed at the time of laparotomy and repair of the bladder.

Several series have reported fewer complications, such as fistula, failure to heal, clot retention, and sepsis, with open repair versus conservative management for patients with blunt extraperitoneal bladder injuries (Cass, 1989; Kotkin and Koch, 1995). In a recent contemporary series comparing operative and conservative management, cystorrhaphy performance resulted in fewer urologic complications such as fistula formation, decreased hospital length of stay, and a decreased time to negative cystography (Johnsen et al., 2016). **For this reason, blunt extraperitoneal injuries in the presence of complicating features (see Key Points in this section) warrant immediate open repair to prevent complications such as fistula, abscess, and prolonged leak.**

For patients undergoing exploratory laparotomy for other associated injuries or internal fixation of pelvic fracture, it is prudent to perform surgical repair of the extraperitoneal rupture at the same setting. The anterior bladder wall is entered directly in the midline, and the tear is closed intravesically with absorbable suture. The perivesical pelvic hematoma should not be disturbed. When internal fixation of pelvic fractures is performed, concomitant bladder repair is recommended because urine leakage from the injured bladder onto the orthopedic fixative hardware is prevented, reducing the risk for hardware infection. Drainage of the repaired bladder can be safely accomplished with a large-bore Foley catheter alone, and cystography performed 1 week after repair should verify bladder healing.

Key Points: Indications for Immediate Repair of Bladder Injury

- Intraperitoneal injury from external trauma
- Penetrating or iatrogenic nonurologic injury
- Inadequate bladder drainage or clots in urine
- Bladder neck injury
- Rectal or vaginal injury
- Open pelvic fracture
- Pelvic fracture requiring open reduction and internal fixation
- Selected stable patients undergoing laparotomy for other reasons
- Bone fragments projecting into the bladder

Penetrating or intraperitoneal injuries resulting from external trauma should be managed by immediate operative repair. In a national study of patients with bladder trauma, operative repair was associated with a 59% reduction in mortality (Deibert and Spencer, 2011). These injuries are often larger than suggested on cystography and are unlikely to heal spontaneously. A prolonged leak of urine may cause a chemical peritonitis or abscess. Select patients with isolated intraperitoneal bladder injuries may undergo laparoscopic repair (Kim et al., 2008). **When bladder injuries are explored after penetrating trauma without preliminary imaging, the ureteral orifices should be inspected for clear efflux; ureteral integrity also may be ensured by intravenous administration of indigo carmine, methylene blue, fluorescein green, or retrograde passage of a ureteral catheter.** Any penetrating injury involving the ureteral orifice or intramural ureter warrants primary closure with stented reimplantation of the ureter and a perivesical drain. In patients with intraperitoneal rupture, antimicrobial agents are administered for

3 days in the perioperative period only. If the bladder has been repaired, a cystogram can be obtained 7 to 10 days after surgery (Corriere and Sandler, 1989). **Several additional studies have shown that suprapubic tube drainage provides no benefit over urethral catheter drainage alone** (Alli et al., 2003; Parry et al., 2003; Thomae et al., 1998; Volpe et al., 1999), thus recent guidelines have suggested catheter drainage alone to be sufficient for management (AUA Urotrauma Guidelines, Statement 18). When concurrent rectal or vaginal injuries exist, the organ walls should be separated, overlapping suture lines should be avoided, and every attempt should be made to interpose viable tissue in between the repaired structures. Fibrin sealant injected over the bladder wall closure may help reduce complications when intervening tissue is unavailable (Evans et al., 2003).

Outcomes and Complications

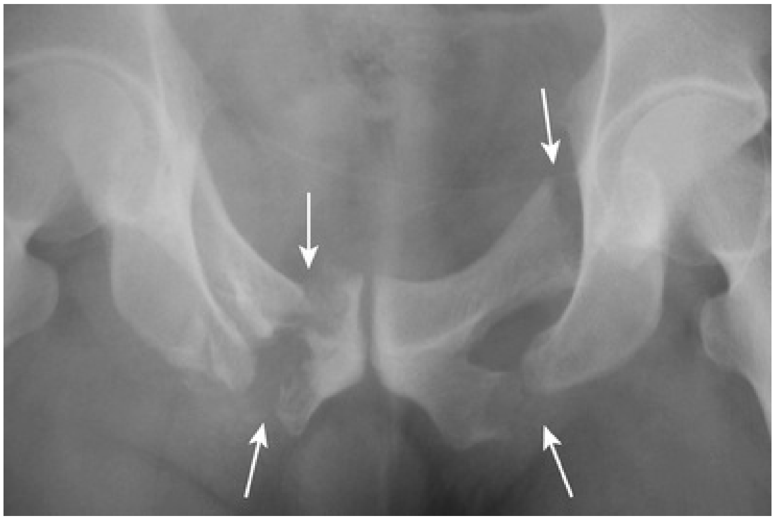
Prompt diagnosis and appropriate management of bladder injuries promote excellent results and minimal morbidity. Serious complications are usually associated with delayed diagnosis or treatment because of misdiagnosis, delayed presentation, or complex injuries resulting from devastating pelvic trauma. Unrecognized bladder injuries may manifest as acidosis, azotemia, fever and sepsis, low urine output, peritonitis, ileus, urinary ascites, or respiratory difficulties. Unrecognized bladder neck, vaginal, and rectal injury associated with bladder rupture can result in incontinence, fistula, stricture, and difficult delayed major reconstruction. Severe pelvic fractures may cause a transient or permanent neurologic injury and result in voiding difficulties despite an adequate bladder repair.

Urethral Injury

Posterior Urethral Injuries

Etiology

Pelvic fracture urethral injury (PFUI) typically occurs in conjunction with multisystem trauma from motor vehicle accidents, falls, or industrial accidents. Fracture of the anterior pelvic ring or pubic diastasis is usually present when urethral disruption is encountered, and a greater degree of displacement has been correlated to a higher risk for urethral injury (Basta et al., 2007). **“Straddle fractures” (eFig. 133.16) involving all four pubic rami and fractures resulting in vertical and rotational pelvic instability are associated with the highest risk for urologic injury** (Brandes and Borelli, 2001; Koraitim, 1999; Mundy, 1996). Urethral injury has been reported to occur in approximately 10% of male patients and up to 6% of female patients with pelvic fractures (Black et al., 2006; Koraitim, 1999). Girls younger than 17 years of age have a higher risk for urethral injury compared with women, perhaps because of greater compressibility of the pelvic bones (Hemal et al., 1999).



EFIG. 133.16 Anteroposterior film of the pubis shows a straddle fracture involving all four pubic rami *(arrows)* in a patient with a posterior urethral disruption in whom initial perineal posterior urethroplasty failed because of severe bone distortion. Reconstruction was successfully performed by an abdominoperineal technique.

Because the posterior urethra is densely adherent to the pubis via the urogenital diaphragm and the puboprostatic ligaments, the bulbomembranous junction is more vulnerable to injury during pelvic fracture than the prostatomembranous junction (Brandes and Borelli, 2001; Colapinto and McCallum, 1977)**. Endoscopic and urodynamic evaluation has confirmed that the membranous urethral sphincter complex tends to remain functionally intact while being avulsed vertically, posteriorly, or laterally from the underlying bulb** (Andrich and Mundy, 2001; Mundy, 1997). In children, injuries are less common (Tarman et al., 2002) but are more likely to extend proximally to the bladder neck because of the rudimentary nature of the prostate (Al-Rifaei et al., 1991; Boone et al., 1992; Devine et al., 1989).

Diagnosis

Examination.

Urethral disruption is heralded by the triad of an inability to urinate, blood at the meatus, and a palpably full bladder. Because these and other classic findings, such as a “high-riding” prostate or a “butterfly” perineal hematoma, may frequently be absent or difficult to discern (Esposito et al., 2005; Sandler and Corriere, 1989), urethral disruption is often first detected when a urethral catheter cannot be placed by the trauma team or when it is misplaced into a pelvic hematoma. Pelvic hematoma often obscures the prostatic contour, resulting in misdiagnosis of an impalpable prostate (Koraitim et al., 1996). Although more rare than in male counterparts, female patients also may develop proximal urethral avulsion injuries. They present with vulvar edema (Fig. 133.17) and blood at the vaginal introitus, indicating the need for careful vaginal examination in all female patients with pelvic fracture (Perry and Husmann, 1992).

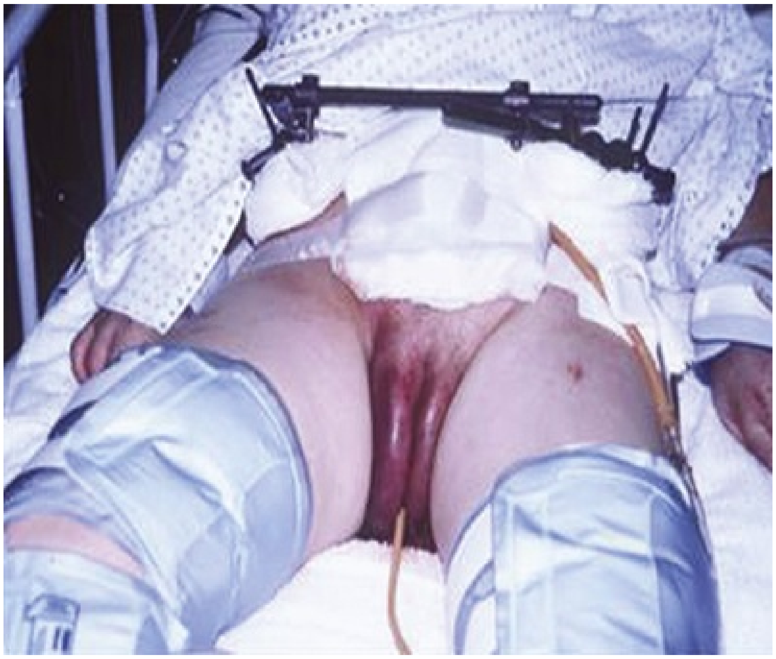


FIG. 133.17 Pelvic fracture urethral disruption injury and marked vulvar edema and ecchymosis in a female patient.

Urethrography.

When blood at the urethral meatus is discovered, an immediate retrograde urethrogram should be performed to rule out urethral injury (Fig. 133.18) (AUA Urotrauma Guidelines, Statement 19). A small-bore (16-Fr) urethral catheter is placed unlubricated 1 cm into the fossa navicularis, and the balloon is filled with 3 mL of water to achieve a snug fit (Sandler and Corriere, 1989). Alternatively, a Brodney clamp or rolled gauze bandage can be used to provide penile traction. Patients should be placed in an oblique or lateral decubitus position, and it is preferable to perform the study under fluorography when it is available; 25 mL of contrast medium is injected gently by a 60-mL catheter-tip syringe, and the film is taken during injection. **Direct inspection by urethroscopy is suggested in lieu of urethrography in female patients with suspected urethral injury** (Koraitim, 1999; Perry and Husmann, 1992).

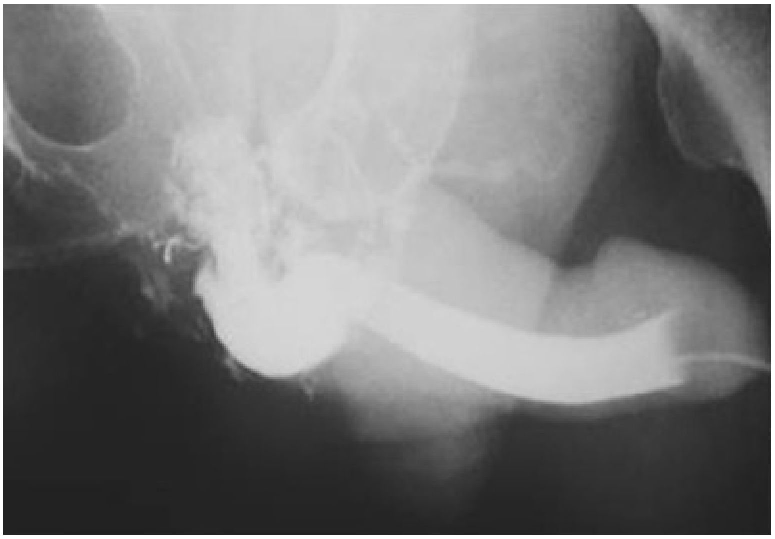

FIG. 133.18 Retrograde urethrogram in a patient with a pelvic fracture shows complete disruption of the posterior urethra.

Initial Management

Initial Management: Suprapubic Cystostomy With Planned Delayed Reconstruction.

Immediate suprapubic tube placement remains the standard of care in men with severe posterior urethral injuries. Percutaneous suprapubic tube placement is safe and expedient when the bladder is obviously distended and no other indications for surgery exist. We prefer a 16-Fr Foley catheter placed via a peel-away sheath trochar in the lower midline, using a preliminary 18G spinal needle and Trendelenberg positioning as adjuncts. Smaller “punch” suprapubic tubes are less robust, tending to fracture or obstruct with debris requiring urgent replacement within several weeks. Alternatively, an infraumbilical incision allows direct inspection and repair of concomitant bladder injury with placement of a large-bore catheter at the bladder dome. Delayed urethral reconstruction may then be performed on an elective basis within several months when the patient is ambulatory.

Increasingly, patients with pelvic ring fracture undergo early surgical fixation by orthopedists to decrease bleeding, improve healing, and speed ambulation (Connor et al., 2003)**. Although orthopedists may suggest that a suprapubic tube not be placed if anterior pubic hardware is anticipated because of concern that the suprapubic tube will lead to hardware infection** (Patterson, 1995)**, we and others** (Bepple et al., 2007; Borrelli and Brandes, 2004) **have**

repeatedly found that suprapubic cystostomy can be used safely without complications throughout the course of care (Fig. 133.19) (AUA Urotrauma Guidelines, Statement 21). When transurethral access to the bladder is compromised because of injury, and the pelvic fracture is managed by open reduction internal fixation, we place a large-bore (24-Fr) Foley catheter in the bladder, tunneled through the skin as high on the lower abdominal midline to keep the tube away from the plated symphysis.

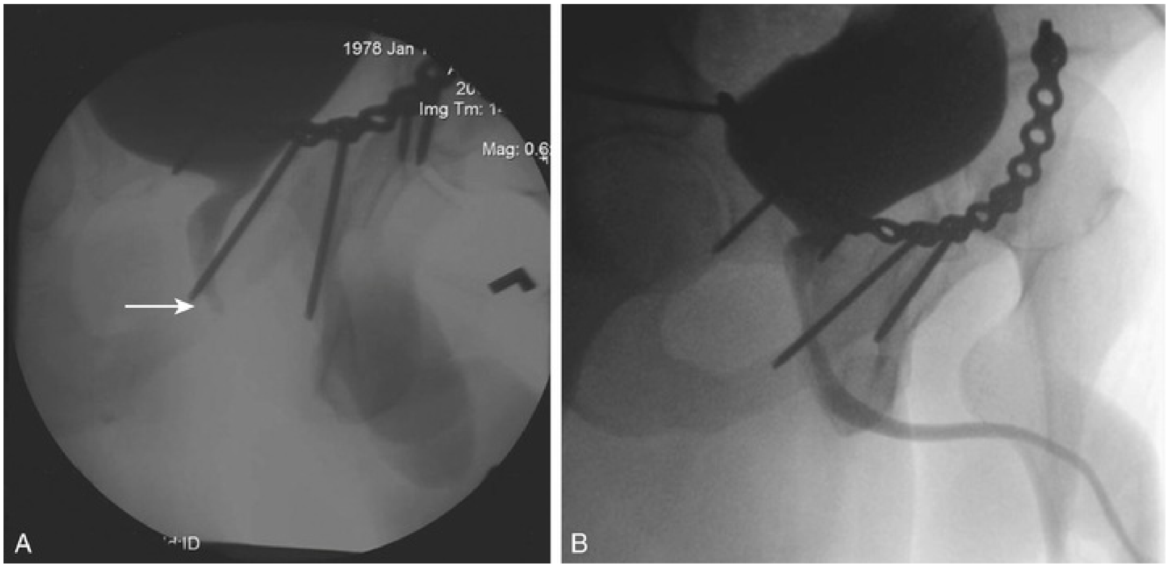

FIG. 133.19 (A) Defect in the urethra *(arrow)* seen on an antegrade urethrogram in a patient after pelvic fracture urethral disruption and internal fixation of anterior pelvic fracture. (B) Postoperative voiding urethrogram demonstrates normal-caliber urethra after perineal urethroplasty.

Initial Management: Primary Realignment.

A brief attempt at primary realignment of the urethral injury is recognized as an alternative option in patients whose condition is stable (AUA Urotrauma Guidelines, Statement 22; Elliott and Barrett, 1997) **and can be done either acutely or within several days of injury.** Combined retrograde and anterograde flexible cystoscopes have been advocated for realignment (Asci et al., 1999; Elliott and Barrett, 1997; Follis et al., 1992; Hadjizacharia et al., 2008; Leddy et al 2012; Mouraviev et al., 2005; Porter et al., 1997; Routt et al., 1996), although prolonged endoscopic realignment attempts risk infection (Morey et al., 1999) and are thus not recommended (Fig. 133.20, AUA Urotrauma Guidelines, Statement 22).

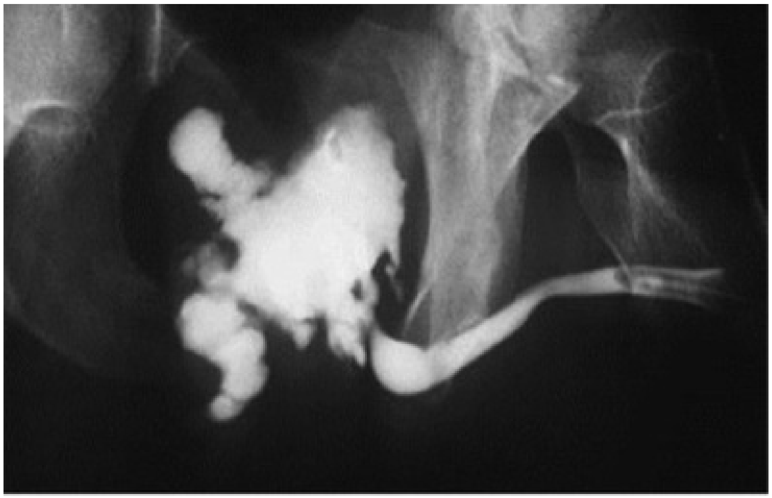

FIG. 133.20 Pelvic abscess diagnosed on retrograde urethrogram in a patient who underwent initial primary endoscopic realignment for urethral disruption.

After realignment, when the urethral catheter is removed after 4 to 6 weeks, it is imperative to retain a suprapubic catheter because an overwhelming majority of patients, despite realignment, will develop posterior urethral stenosis (Chung et al., 2018; Leddy et al., 2012). If the patient voids satisfactorily through the urethra, the suprapubic catheter can be removed 7 to 14 days later. Primary realignment rarely heals without stricture (Elliott and Barrett, 1997; Leddy et al., 2012). Whether realigned or not, urethral stenosis 1 to 2 cm in length typically ensues in an overwhelming majority of PFUI patients (Asci et al., 1999; Chung et al., 2018; Kotkin and Koch, 1996; Routt et al., 1996), requiring elective delayed posterior urethroplasty (Kotkin and Koch, 1996; Mouraviev et al., 2005). Further endoscopic treatments or dilations of PFUI are recognized as being costly and prone both to failure and adding complexity to the eventual repair (Horiguchi et al., 2017; Tausch et al., 2017). Multi-institutional investigation is currently underway to further assess the comparative treatment efficacy of immediate realignment to immediate suprapubic tube placement with delayed urethroplasty.

Incomplete urethral tears are best treated by stenting with a urethral catheter. Various investigators (Al-Ali and Husain, 1983; Kotkin and Koch, 1996; Mundy, 1991) **have not identified evidence that a gentle attempt at urethral catheterization converts an incomplete transection into a complete transection.** Caution is warranted because misplacement outside the bladder is theoretically possible; radiographic confirmation of adequate positioning is imperative. In no case should traction be used after urethral catheter placement as it may cause incontinence (Asci et al., 1999).

Delayed Reconstruction

In posterior urethral disruption, the rupture defect between the two severed ends fills with scar tissue, resulting in a complete lack of urethral continuity. This separation is not a stricture; it is a true urethral stenosis filled with fibrosis. **At 2 to 3 months, scar tissue at the urethral disruption site is stable enough to allow posterior urethroplasty to be undertaken safely, provided that associated injuries are stabilized and the patient is ambulatory.** Suprapubic cystostomy drainage should be maintained until any associated injuries have healed and the patient can be appropriately positioned for the reconstructive procedure.

Preoperative Evaluation.

Before the reconstructive procedure is planned, imaging studies are necessary to delineate the characteristics of the urethral rupture defect. **A cystogram and retrograde urethrogram should be obtained simultaneously ("up-and-down-o-gram," Fig. 133.21).** The patient is asked to attempt to void with the bladder filled. Ideally, the prostatic urethra should be visualized as the bladder neck opens, enabling measurement of the distance between the severed urethral ends. If the bladder neck does not open, flexible endoscopy should be used to supplement radiographic imaging (Mundy, 1997). The appearance of the bladder neck on preoperative imaging may not correlate with bladder neck behavior postoperatively (Koraitim, 2010; Mundy, 1997), making it difficult to predict bladder neck incompetence or obstruction. MRI has been employed to define the length of the defect and to determine the extent and direction of urethral dislocation (Dixon et al., 1992) and the extent of prostatic displacement, and it may help in planning the surgical approach (Koraitim and Reda, 2007).

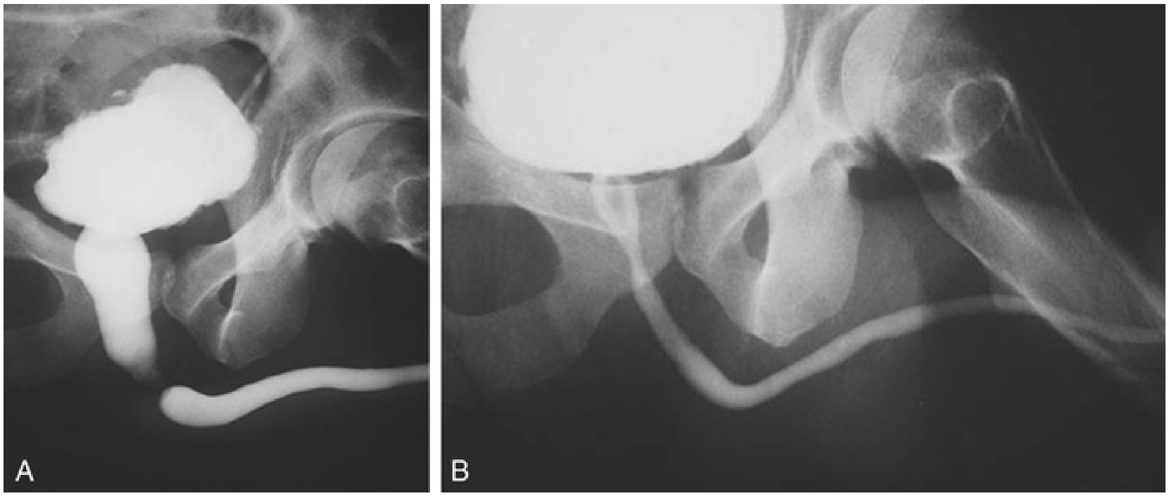

FIG. 133.21 (A) Combined cystogram and urethrogram 4 months after pelvic fracture shows complete posterior urethral disruption injury. (B) Postoperative appearance reveals normal urethral caliber.

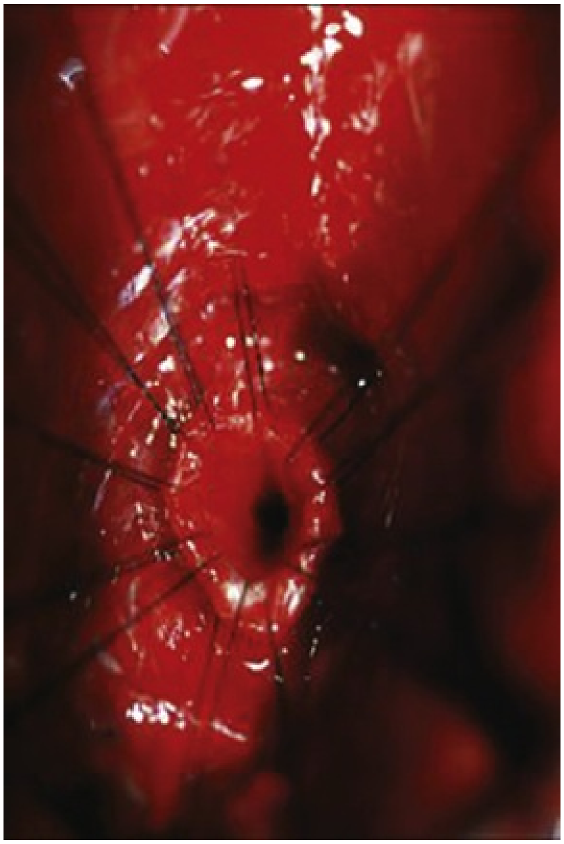
Endoscopic Treatment

Endoscopic treatments such as direct-vision internal urethrotomy are best reserved for select short, incomplete urethral stenoses, such as partial distraction injuries for which early catheterization has maintained initial urethral continuity. When preoperative evaluation indicates defects 1 cm or longer, endoscopic procedures such as cutting through the pelvic scar to provide a channel between the two ends of the avulsed urethra ("cut-to-the-light" procedure) tend to be ineffective. Aggressive endoscopic treatments have been associated with complications such as coring of a false passage that inadvertently bypasses the bladder neck (Turner-Warwick, 1989). Cut-to-the-light or similar core-through procedures typically require multiple urethrotomies or long-term dilation by the patient and/or urologist to keep the channel open. Inevitably, the fibrosis contracts, leading to difficult self-catheterization, false passage, and/or acute urinary retention. In such cases, a 2- to 3-month period of "urethral rest" via suprapubic urinary diversion is advised before open reconstruction (Terlecki et al., 2011).

Surgical Reconstruction

Open posterior urethroplasty through a perineal anastomotic approach is the treatment of choice for most urethral distraction injuries because it definitively cures the patient without the need for multiple procedures. When preoperative studies have determined that the prostatic urethral apex can be reached by a perineal approach, the patient is placed in the high lithotomy position, and a midline or lambda-shaped incision is made. The bulbar urethra is freed and mobilized from the site of urethral rupture to the midscrotum. The scar tissue of the urethral rupture defect is excised, and the prostatic urethra is identified at the apex of the prostate. Care must be taken to excise carefully and meticulously all fibrotic tissue from the proximal urethral margin until at least a 28-Fr bougie passes without resistance (eFig. 133.22) (Morey and McAninch, 1997; Turner-Warwick, 1989). The bulbar urethra is then anastomosed in a tension-free manner to the prostatic urethra.



EFIG. 133.22 Intraoperative view of normal membranous urethra after fibrotic tissue was excised during perineal bulbomembranous urethroplasty.

Posterior urethral anastomosis is successfully achieved in a majority of cases through a perineal approach alone (Carr and Webster, 1997; Kizer et al., 2007)**. Adjunctive maneuvers such as corporal splitting, inferior pubectomy, and corporal rerouting are often implemented if direct anastomosis proves difficult** (Flynn et al., 2003; Mundy, 1997)**. Others have found these**

maneuvers, especially supracrural rerouting, to be unnecessary and/or unhelpful in many cases (Cooperberg et al., 2007; Kizer et al., 2007; Morey and McAninch, 1997; Rosenstein and Jordan, 2003).

Total removal of the symphysis pubis, first reported by Pierce in 1962, has been recommended when severe injuries result in complicating features such as fistula or marked displacement or retropubic fixation of the prostate (Asci et al., 1999; McAninch, 1989; Netto, 1985; Pierce, 1962). **Alternatively, a combined abdominoperineal approach (with or without partial pubectomy) has proven helpful in cases of severe fibrosis, fistula, previous failed anastomotic urethroplasty, and associated bladder neck injury, and in pediatric cases** (Al-Rifaei et al., 1991; Koraitim, 2003, 2005; Pratap et al., 2006; Waterhouse, 1976). It is important to limit the lithotomy time to 5 hours or less to prevent lower extremity complications when any complex urethral reconstruction is undertaken (Anema et al., 2000).

Complications: Erectile Dysfunction.

Some degree of impotence is noted in as many as 82% of patients with pelvic fracture and urethral distraction injury (Flynn et al., 2003)**, although the average reported rate is approximately 50%** (Asci et al., 1999; Blaschko et al., 2015; Corriere et al., 1994; Elliott and Barrett, 1997; Koraitim, 2005; Routt et al., 1996)**. The etiology is multifactorial and variably attributed to cavernous nerve injury, arterial insufficiency, venous leak, and direct corporal injury** (Munarriz et al., 1995; Narumi et al., 1993; Shenfeld et al., 2003). Factors that correspond to the severity of the injury, such as diastasis of the pubic symphysis, lateral displacement of the urethra, and long urethral gap, have been found to correlate with erectile dysfunction (Feng et al., 2008; Koraitim, 2013).

Some surgical series have shown a small number of patients with new-onset or worsened erectile dysfunction after reconstruction (Tunc et al., 2000); however, the complications of the original pelvic injury are difficult to differentiate from the complications of attempts to repair urethral and bladder injuries. Accounts of greater risk for erectile dysfunction and incontinence with primary realignment were published before the advent of flexible endoscopes (Koraitim et al., 1996). Several studies have shown that patients treated with modern techniques of primary endoscopic realignment have rates of impotence and incontinence similar to those of patients who have had either no treatment or delayed open reconstruction (Asci et al., 1999; Koraitim, 2005; Kotkin and

Koch, 1996; Mouraviev et al., 2005). **These studies support the conclusion that these complications are usually the result of the injury itself and not of the treatment** (Barrett et al., 2014; Corriere, 2001; Elliott and Barrett, 1997; Follis et al., 1992; Porter et al., 1997). Some patients who become impotent after injury spontaneously recover erectile function 1 or 2 years later (Koraitim, 2005; Morey and McAninch, 1997; Turner-Warwick, 1989).

Many patients who become impotent as a result of pelvic fracture have some degree of arterial insufficiency (Armenakas et al., 1993; Matthews et al., 1995). **Because patients with impotence may be more vulnerable to restenosis after posterior urethroplasty as a result of bulbar urethral ischemia, some experts have suggested that "at-risk" patients undergo preoperative penile arterial duplex Doppler studies to identify candidates who are suitable for initial penile revascularization** (Matthews et al., 1995; Rosenstein and Jordan, 2003; Zuckerman et al., 2012). However, indications for penile revascularization as a treatment for post-traumatic erectile dysfunction are extremely limited (Kawanishi et al., 2004). Overall rates of incontinence, anejaculation, and areflexic bladder are low (2% to 4%) (Anger et al., 2008; Asci et al., 1999; Corriere et al., 1994; Elliott and Barrett, 1997), although these conditions along with erectile dysfunction must be monitored for at least 1 year after urethral injury (AUA Urotrauma Guidelines, Statement 23).

Complications: Recurrent Stenosis.

After posterior urethroplasty, 5% to 15% of patients have recurrent stenosis at the anastomosis (Cooperberg et al., 2007; Flynn et al., 2003; Koraitim 2005; Mundy, 1996). Endoscopic treatment (e.g., with direct-vision internal urethrotomy) is often successful in this setting because most fibrotic tissue has been eliminated (Cooperberg et al., 2007; Koraitim 2003; Netto et al., 1989).

Complications: Incontinence.

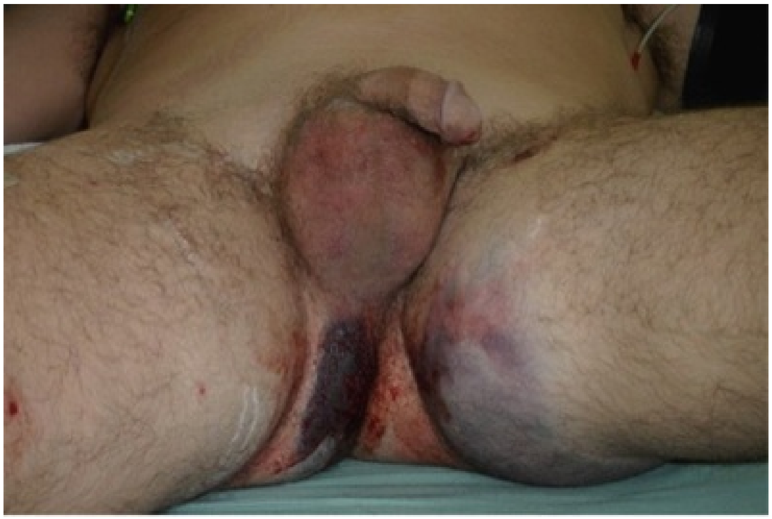
Urinary continence after urethral distraction is the rule rather than the exception, despite destruction of the external sphincter from either the injury itself or the subsequent repair. Incontinence rates after reconstruction are low—less than 4% (Koraitim, 2005). The mechanism of continence is thought to be largely attributable to bladder neck function (Iselin and Webster, 1999). Urodynamic data show that a significant proportion of patients also have identifiable distal rhabdosphincteric function (Whitson et al., 2008).

Anterior Urethral Injuries

Etiology

In contrast with posterior urethral distraction, anterior injuries are most often isolated (Kiracofe et al., 1975). Most occur after straddle injury and involve the bulbar urethra, which is susceptible to compressive injury because of its fixed location beneath the pubis. A smaller percentage of injuries to the anterior urethra are the result of direct penetrating injury to the penis.

As with posterior urethral injury, a high index of suspicion must be maintained in all patients with blunt or penetrating trauma in the urogenital region, and urethrography should be performed in any case of suspected urethral injury (Husmann et al., 1993). Clinical signs of anterior urethral injuries include blood at the meatus, perineal hematoma, gross hematuria, and urinary retention. Similar to pelvic fracture urethral injury cases, prompt urinary drainage must be established through either suprapubic tube placement or urethral catheterization with fluoroscopic assistance (AUA Urotrauma Guidelines, Statement 25). In severe trauma, Buck's fascia may be disrupted, resulting in blood and urinary extravasation into the scrotum (eFig. 133.23). **The primary morbidity of straddle injury is urethral stricture, which may become symptomatic years later** (Park and McAninch, 2004).



EFIG. 133.23 Extravasation of blood in the scrotum and perineum seen on physical examination in a patient with a straddle injury.

Initial Management

Armenakas and McAninch (1996) proposed a simple, practical classification scheme dividing anterior urethral injuries on the basis of radiographic findings into contusion, incomplete disruption, and complete disruption. Contusions and incomplete injuries can be treated with urethral catheter diversion alone. **Initial suprapubic cystostomy is the standard of care for major straddle injuries involving the urethra** (Park and McAninch, 2004); however, primary anterior urethral realignment has shown promising results with respect to stricture rate and erectile dysfunction in patients with straddle injuries of lesser magnitude (Ying-Hao et al., 2000; Yu et al., 2007).

Primary surgical repair is recommended for low-velocity urethral gunshot injuries (Kunkle et al., 2008); catheter alignment alone is associated with a far worse stricture rate (Husmann et al., 1993). Debridement of the corpus spongiosum after trauma should be limited because corporal blood supply is usually robust, enabling spontaneous healing of most contused areas (Kiracofe et al., 1975; Husmann et al., 1993). Initial suprapubic urinary diversion is recommended after high-velocity gunshot wounds to the urethra, followed by delayed reconstruction.

Delayed Reconstruction

Before any planned procedure, a retrograde urethrogram and voiding cystourethrogram should be obtained to define the site and length of the obliterated urethra clearly. Urethral ultrasound examination may help delineate the length and severity of stricture. Retrograde injection of saline combined with antegrade bladder filling fills the urethra proximally and distally, and a 10-MHz sonogram clearly defines the nondistensible segment to be excised. Dense fibrous tissue from trauma often demonstrates a fixed, nondistensible appearance sonographically with significant shadowing (Morey and McAninch, 2000). **Ultrasound imaging of urethral strictures is more accurate than retrograde urethrography** (Mitterberger et al., 2007), although it is highly operator dependent and not widely used at the present time.

Anastomotic urethroplasty is the procedure of choice in the totally obliterated bulbar urethra after a straddle injury. The typical scar is 1.5 to 2 cm long and can be readily completely excised. The proximal and distal urethra can be mobilized for a tension-free, end-to-end anastomosis. This is a highly successful procedure in more than 95% of cases (Jordan et al., 2010; Santucci et

al., 2002).

Endoscopic incision of saddle injuries through the scar tissue of an obliterated urethra is a hopeless procedure doomed to failure. Partial urethral narrowing can initially be treated by endoscopic incision or dilation with greater success. **Repeated endoscopic manipulation is neither clinically effective nor cost-effective for the treatment of urethral strictures** (Greenwell et al., 2004). Patients who undergo repeated endoscopic procedures are also more likely to require complex reconstructive procedures such as grafts (Hudak et al., 2012; Park and McAninch, 2004). Open repair should be delayed for several weeks after instrumentation to allow the urethra to stabilize, and a 2-month period of suprapubic urinary diversion may be prudent preoperatively to optimize conditions for repair of complex or recurrent strictures that have been catheter dependent (Terlecki et al., 2011). Finally, UroLume stents (now “off the market” in the United States) are contraindicated in the setting of traumatic urethral strictures (Wilson et al., 2002).

Key Points: Lower Genitourinary Tract Injuries

- Although most bladder injuries are associated with pelvic fractures, only 10% of patients with pelvic fracture have bladder injuries.
- Intraperitoneal bladder injury from external trauma requires urgent operative repair.
- Prompt suprapubic catheter drainage is recommended for initial management of pelvic fracture urethral disruption injury.
- Primary realignment may be performed in stable patients; close follow-up is essential because of the high rate of stricture formation.
- Posterior urethroplasty by excision and primary anastomosis is the treatment of choice for urethral distraction injuries.
- Anastomotic urethroplasty is the procedure of choice for straddle injury–related anterior urethral stricture.

Special Urologic Considerations in Transgender Individuals

Nicolas Lumen MD, PhD, Anne-Françoise Spinoit MD, PhD, Piet Hoebeke MD, PhD

Gender identity is a person's sense of gender, which can be nonconforming with the sex a person was assigned at birth, inclusive of the associated gender role and/or primary and secondary sex characteristics. Whereas sex of a person refers to biologic differences (chromosomes, hormonal profiles, internal and external sex organs), **gender describes the characteristics that a society or culture delineates as masculine or feminine.**

When gender identity and sex do not match in a person, we discuss gender dysphoria (GD). When the GD reaches a significant level of distress, it can meet the criteria for a formal diagnosis: transsexualism in the International Classification of Diseases, 10th edition (ICD-10) or gender identity disorder (GID) in the Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-4) recently adapted in DSM-5 (American Psychiatric Association, 2013) to gender dysphoria (Black and Grant, 2014; De Cuypere et al., 2011; Dittmann et al., 1996).

The largest epidemiologic study and review about transsexualism reports prevalence ranging from 1 : 11,900 to 1 : 45,000 for male-to-female (transwomen) persons and 1 : 30,400 to 1 : 200,000 for female-to-male (transmen) persons (De Cuypere et al., 2007). Recently, an increase in prevalence is observed together with more public awareness and more research into the diagnosis and treatment. During the past decade, there is also an increase in transgender and gender nonconforming (TGN) youth (Steensma et al., 2011).

The etiology of transsexualism remains unknown but is thought to be multifactorial. Probably, its etiology is both biologic (“nature”), where brain, genetic factors, and hormones might play a role, and dependent on external psychological influence (“nurture”) (Bao and Swaab, 2011; Green, 2000; Hoekzema et al., 2015).

Since 1979, generally accepted treatment guidelines have been published by the World Professional Association for Transgender Health (WPATH), with the latest guidelines published in 2012 (WPATH Standards of Care Version 7: https://www.wpath.org/publications/soc) (Bockting et al., 2011).

In most but not all patients, treatment includes surgical management known as sex reassignment surgery (SRS) or gender-affirmation surgery (GAS), which can include genital surgery and removal of gonads, mastectomy or breast augmentation, facial feminization surgery, and speech modification surgeries. **Because of the close relationship between the genital and the urinary tract both in males and females, genital surgery includes modifications of the urinary tract. GAS can have an impact on the urinary tract, which justifies a chapter on specific urologic considerations in TGN individuals.** It is, however, important to note the difference between SRS and gender reassignment surgery (GRS). GRS refers to the whole body including the genitals; facial and body procedures are included. SRS refers only to the genital procedures (vaginoplasty, clitoroplasty, labioplasty, phalloplasty, penile-scrotal reconstruction). This chapter will focus only on SRS.

Urologic Issues in Gender Nonconforming Youths

In the past decades, more children and adolescents present to health care with gender nonconforming symptoms. There is a bimodal peak at presentation, with children presenting with severe gender dysphoria and adolescents who present at or just after puberty (Conard, 2017). Often these youths present with atypical symptoms like mood and behavior problems. Furthermore they often face bullying and harassment at home, at school, and in the community. One matched retrospective cohort study found a twofold to threefold increased risk for depression, anxiety disorder, suicidal ideation, suicide attempt, and self-harm (Reisner et al., 2015).

These patients will not present to urology or pediatric urology practices, but urologists should be aware that there are treatment guidelines for these youths covering social transition, the use of puberty blockers, and gender-affirming hormones and surgery (Hembree et al., 2009).

In most countries, surgery is only possible when the patient reaches the age of majority, although in some countries chest surgery and removal of gonads is possible from 16 years of age onward. It can be expected that with the wide availability of treatment in youths more and more adolescents will present for GAS.

So, in gender nonconforming youths, urologic issues are rare. We have, however, observed that some patients present with lower urinary tract symptoms (LUTS) because of changed toilet behavior. As some patients tend to avoid going to the toilet in public, they tend to develop detrusor underactivity (unpublished observations).

Puberty-blocking and gender-affirming hormones might have an impact on the techniques of GAS. We have observed in transwomen that, as a result of puberty blocking, the penis is underdeveloped and penile skin is lacking for penile inversion vaginoplasty, making additional bowel vaginoplasty necessary to obtain a functional vagina. In transmen, the estrogen naïvety of the vagina makes vaginectomy much more complicated. So the actual care of TGN youth can have an impact on future results of GAS (unpublished observations).

Urologic Issues in Male-to-Female Transsexuals (Transwomen)

Genital surgery in transwomen consists in **removal of the testes and penile body and the creation of a vaginal cavity and a clitoris.** Different techniques have been described, however, the penile inversion technique is the most often used technique to create the vaginal cavity (Selvaggi and Bellringer, 2011). During this reconstructive surgery, a cavity is created between the prostate and the rectum with the risk for damaging nerve supply to the sphincter and bladder and damaging the rectum and the bladder.

Effects of Sex Reassignment Surgery on Bladder Sphincter Function

Vaginoplasty in transwomen should create a perineogenital complex as feminine in appearance and function as possible. The urethra should be shortened in such a way that the urinary stream is downward in the sitting position and it should be free of stenosis. Shortening of a male urethra has low complication rates. The **neomeatus can develop meatal stenosis** typical for mucocutaneous connections. When the meatus is patent, there should be no long-term negative effect on the lower urinary tract.

During SRS in transwomen, the bulbospongiosus tissue needs to be resected. If it is not resected, obstruction to the vaginal cavity caused by erection on sexual stimulation and arousal can result. As the urethra is thin at this level, proper care should be taken not to damage the urethra while resecting the bulbospongiosus tissue.

The incidence of LUTS in transwomen is unknown. There have been some reports on meatal and urethral stenosis, infections, deviation of urinary stream, and incontinence (Hoebeke et al., 2005; Kuhn et al., 2007; Melloni et al., 2016).

In a study performed at our center, 16% of transwomen presented on the long-term symptoms of urinary incontinence (Hoebeke et al., 2005).

Fate of the Prostate in Transwomen

The prostate is **not removed** during SRS. After GAS, these transwomen can suffer prostatitis, benign prostatic hyperplasia (BPH), and prostate cancer. In transwomen who underwent vaginoplasty, the prostate can easily be palpated or examined by ultrasonography through the neovagina (Weyers et al., 2009).

Prostatitis

There is no literature on prostate infection in transwomen. Despite this lack of evidence from the literature, cases of prostatitis and a case of prostate abscess has been observed in our center. The lack of reports in the literature probably reflects the **very low incidence.** Prostatitis is often related to BPH, and BPH is rare because of the estrogen treatment. This is the most evident reason for the low incidence.

Benign Prostatic Hyperplasia

Two cases of BPH, requiring transurethral prostate resection, have been described in individuals who had been orchidectomized and treated with estrogens only for more than 20 years (Trum et al., 2015).

Prostate Cancer

Six cases of prostate cancer in transwomen taking estrogen have been reported (for a review, see Trum et al., 2015). It is not clear if these cancers were estrogen-sensitive or were present before the start of estrogen administration and then subsequently de-differentiated to become androgen-independent or estrogen-sensitive. Most of these patients were older than 50 years of age when they started cross-sex hormone treatment (with total androgen ablation). In most clinics, screening for elevated levels of prostate-specific antigen (PSA) is not done routinely. The question could be raised whether a digital rectal examination of the prostate in combination with measuring PSA should be recommended in the follow up of transwomen. The six reported cases of prostate cancers in an unknown number of transwomen set against this incidence **do not lead to an evidence-based recommendation on routine testing.** Most of the reported cases of prostate cancer in transwomen were in individuals who started cross-sex hormones late in life. So digital rectal examination and measurement of PSA may be limited to candidates with a late start of hormone treatment or those with a family history of prostate cancer. Whereas in a male population the upper limit of reference values for PSA is 4 ng/mL, in androgen-deprived people the upper limit should be 1.0 ng/mL and, as in men, the PSA velocity is a significant prognosticator of malignancy.

Urologic Issues in Female-to-Male Transsexuals (Transmen)

A transman can undergo a long care pathway with several invasive procedures in different stages. These procedures can include mastectomy, hysterectomy, ovariectomy, vaginectomy, scrotoplasty, urethroplasty, phalloplasty, and implantation of testicular and erectile prosthesis. According to standards of care, patients do not need to undergo all surgical steps, however, a majority of transmen want to reach the following goals by undergoing surgery (Hage and De Graaf, 1993; Monstrey et al., 2009; Perovic and Djordjevic, 2003):

- Normal-looking male genital appearance
- Voiding in a standing position
- Ability for sexual intercourse

To achieve these goals, participation of a dedicated urologist in the gender team is advisable.

Diagnosis and Preoperative Care

Because SRS in transmen has an impact on the lower urinary tract resulting from vaginectomy, pelvic floor reconstruction, and lengthening of the urethra, preoperative urologic screening is mandatory.

Diagnosis

Diagnosis of GD is made following the WPATH guidelines. Patients need to be referred at centers for GD, where a full multidisciplinary team composed of psychologists, psychiatrists, endocrinologists, gynecologists, social workers, plastic surgeons, and urologists will guide the patient through the diagnostic path that can end in SRS if wished by the patient. One of the important phases before considering SRS is the minimum of 2 years the patient has to live and work in the desired gender. This phase is called the “real-life experience.”

Once the diagnosis is confirmed, the real-life experience has taken place, and extensive counseling has been given about SRS, the patient might choose to undergo the surgical procedures related to it. Interestingly, some patients choose not to undergo SRS and prefer to go on in life in the new gender with their native genitals.

Preoperative Care

When considering SRS, the **urinary tract status should be checked beforehand.** When undergoing SRS, transmen will have significant lengthening of the urethra. Any preexisting lower urinary tract disorder (LUTD) might worsen after lengthening the urethra with a tube based on skin, after vaginectomy, or after pelvic floor reconstruction. Along with a urologic history, uroflowmetry with a postvoid volume is needed to assess preoperative status. Ultrasonography of the kidneys is performed at the same time to exclude any upper tract anomaly such as stones or hydronephrosis, which could be potentially more difficult to treat after SRS.

Transwomen, on the other hand, will only have a shortening of their urethra, which makes them less prone to postoperative LUTD. A preoperative ultrasound evaluation of the urinary tract is sufficient.

The **informed consent** process should include urologic complications. Urinary fistulae and strictures, damage to neighboring structures (e.g., rectum, bladder, urinary sphincter), lower urinary tract dysfunction, and urinary tract infection and complications related to the implants should all be included.

Sex Reassignment Surgery

SRS in transmen can be divided as follows:

1. Removal of female anatomic structures: mastectomy, oophorectomy, hysterectomy, and vaginectomy
2. Reconstruction of male anatomic urogenital structures (genitoperineal transformation): scrotoplasty, urethroplasty, and phalloplasty (or metoidioplasty)
3. Implantation of testicular implants and erectile implant.

Removal of Female Anatomic Structures

Mastectomy, Hysterectomy, and Ovariectomy

Mastectomy is usually the first surgical procedure that will be performed. A subcutaneous mastectomy is performed with removal of the glandular tissue but with preservation of overlying skin and (part of) the nipple. Different types of subcutaneous mastectomy are possible depending on the patient's anatomy and surgeon's experience/preference (Monstrey et al., 2008). To reduce morbidity and scar tissue, ovariectomy and hysterectomy are preferably performed by the laparoscopic approach. If this is not possible, or in case of need of conversion, a Pfannenstiel incision is advised to reduce visible scar tissue. **During hysterectomy, care must be taken not to injure the ureters.** The ureters cross the iliac vessels and run toward the bladder's trigone under the uterine artery. In case of injury to the ureter, the urologist must be asked for immediate repair. The type of repair depends on the extent and location of the injury (Serafetinides et al., 2015). During hysterectomy, there is a small risk for injury of the bladder. If a bladder injury is encountered, immediate repair with resorbable sutures is needed (Lumen et al., 2015). To facilitate the future vaginectomy, it is advised to remove the entire cervix and, if possible, the tip of the vagina during hysterectomy. To minimize the number of procedures, mastectomy, ovariectomy, and hysterectomy can be performed as a combined procedure. This will usually take an admission of 3 to 5 days (Weyers et al., 2010).

Vaginectomy

Vaginectomy is usually combined with genitoperineal transformation in transmen and not done as a separate procedure. The vaginectomy is a **hazardous procedure.** Potential major complications associated with vaginectomy are hemorrhage requiring re-intervention (5.7%), bladder injury (3.1%), and rectal injury (0.9%) (Weyers et al., 2010). Because the severity of these complications and because vaginectomy is not really necessary, it must be discussed with the patient whether or not to perform vaginectomy.

If vaginectomy is chosen, the risk for damage to neighboring organs is highest. The procedure is described in Fig. 134.1. Alternatively, the upper part of the vagina can be kept in place and the mucosa fulgurated to prevent the formation of a mucocele (Fig. 134.2). If it is decided not to perform vaginectomy, the plane between the female urethra and the anterior vaginal wall is dissected over 2 to 3 cm to allow lengthening of the urethra with enough separation from the anterior vaginal wall to prevent urethrovaginal fistulae (Fig. 134.3).

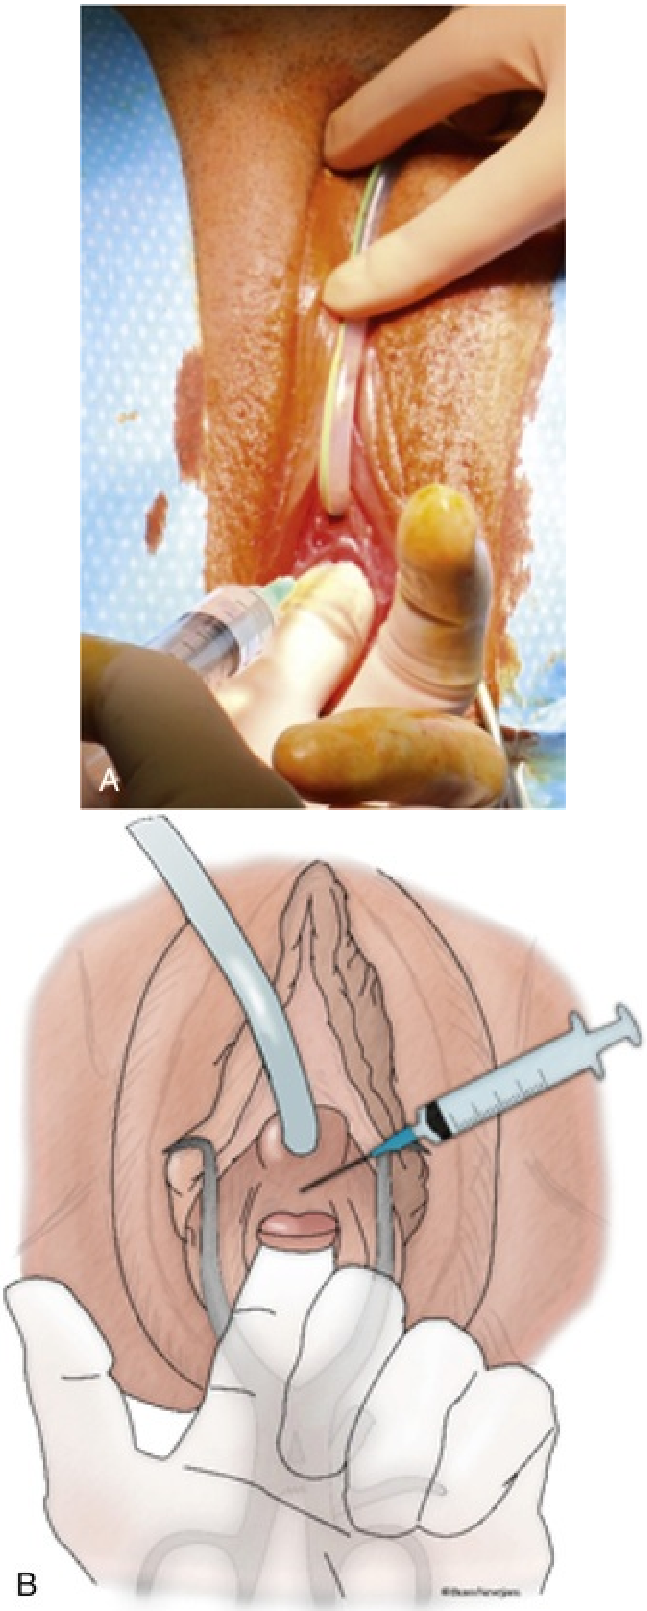

FIG. 134.1 (A and B) Total vaginectomy *(picture and schematic view).* The plane between the anterior vaginal wall and the urethra-bladder is infiltrated with a dilute solution of xylocaine. This hydrodissection will aid in the later

surgical development of this plane.

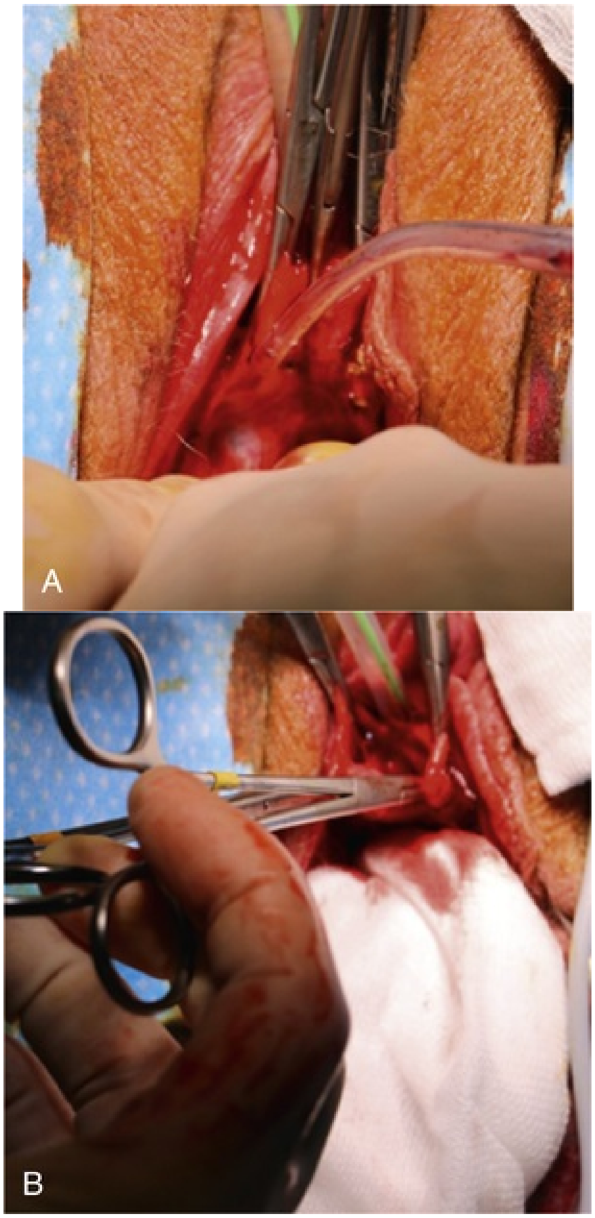

FIG. 134.2 (A) Blunt, digital dissection of the rectovaginal plane. (B) The rectum is protected by a gauze during further vaginectomy.

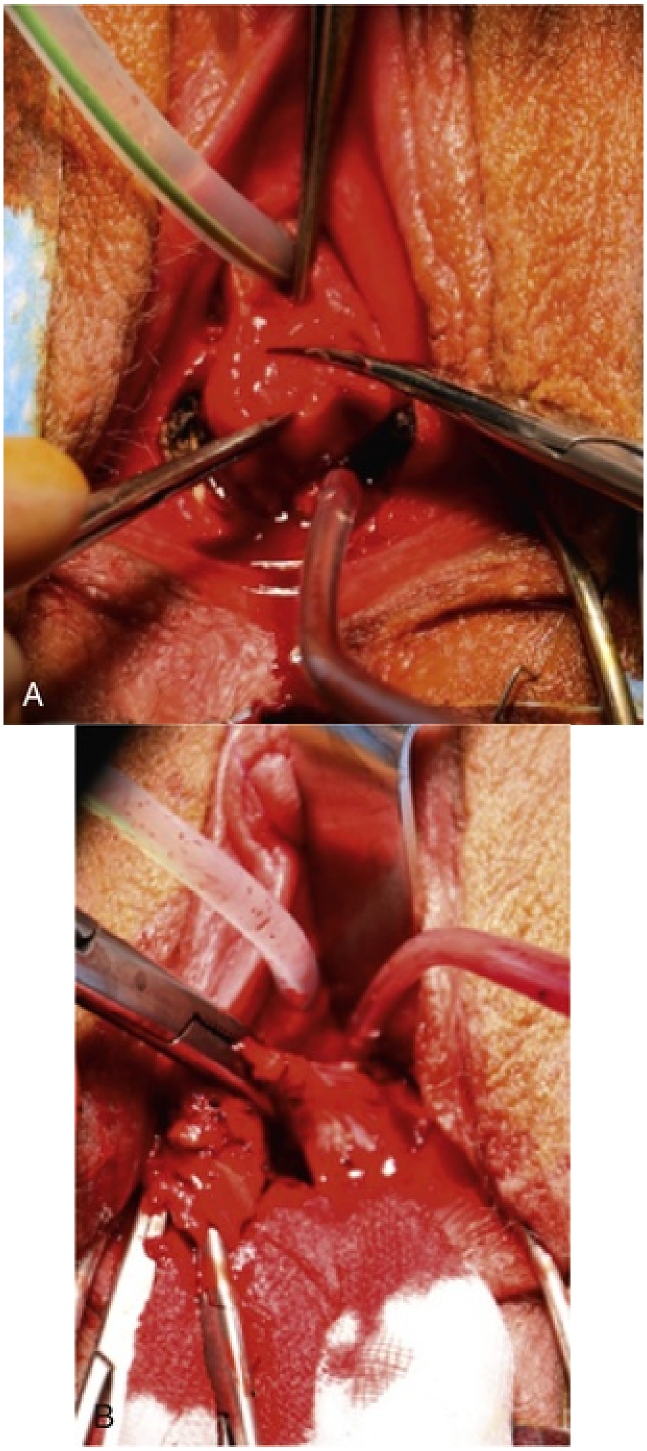

FIG. 134.3 (A) Sharp dissection of the urethrovaginal plane. (B) The lateral vaginal wall is grasped by a Jean-Louis Faure clamp, which facilitates exposure of the levator muscle.

The vaginal introitus is circumferentially incised, and the vagina is grasped with two mosquito clamps anterior and two posterior. The plane between the posterior vaginal wall and the rectum is usually easy to develop by blunt digital dissection. A gauze to protect the rectum is placed in the created space between the rectum and the posterior vaginal wall.

The mobilization between the anterior vaginal wall and the urethra is started with sharp dissection using tenotomy scissors. Diathermy must be avoided to prevent thermal damage to the sphincteric mechanism. Once this plane is finalized, the further plane between the bladder and anterior vaginal wall can be done by the combination of blunt and sharp dissection. A submucosal dissection of the vaginal wall prevents injury to the bladder wall. If injury to the bladder wall occurs, it is usually at the midline, and this must be closed primarily. If there is doubt about the integrity of the ureteric orifices, cystoscopy must be performed. Once the anterior and posterior vaginal walls are sufficiently mobilized, dissection of the lateral walls is started. The mosquito clamps are removed and replaced by two hysterectomy clamps. The levator muscle is dissected away from the lateral wall. High-energy cauterization is used for the lateral dissection to have sufficient hemostasis of the paravaginal plexus.

Although the upper vaginal part can be removed, it is not necessary and less hazardous. The vaginal mucosa is then cauterized to avoid mucosal retention cysts (Fig. 134.4).

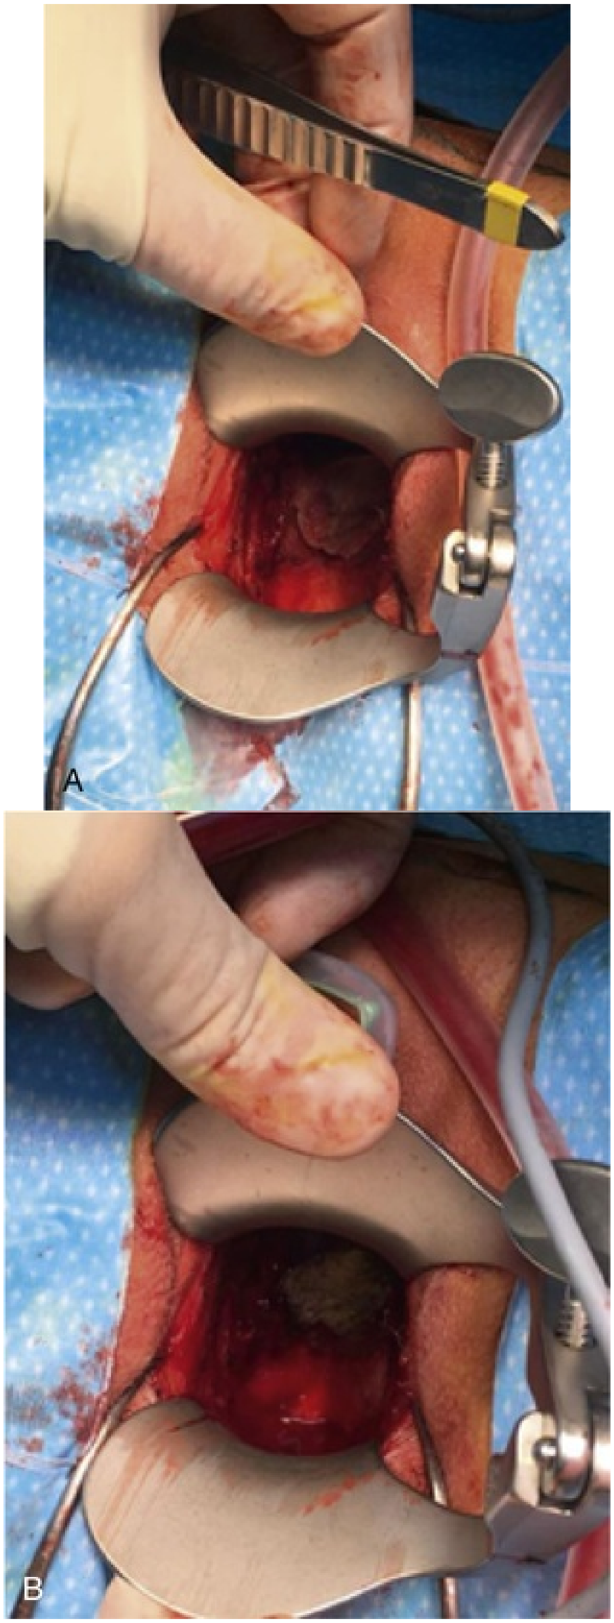

FIG. 134.4 Partial vaginectomy. Vaginal top before (A) and after (B) coagulation.

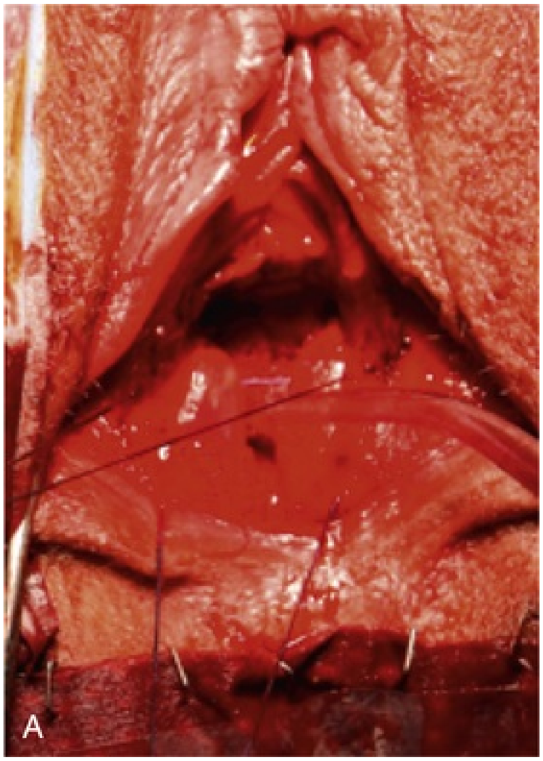
The gauze protecting the rectum is removed, and hemostasis is performed. Hemostatic agents in the space between the rectum and the bladder are useful at this stage. The medial borders of the left and right levator muscle are approximated with two to three Vicryl 1.0 sutures (Fig. 134.5). This to prevent future prolapse of the bladder and/or rectum.



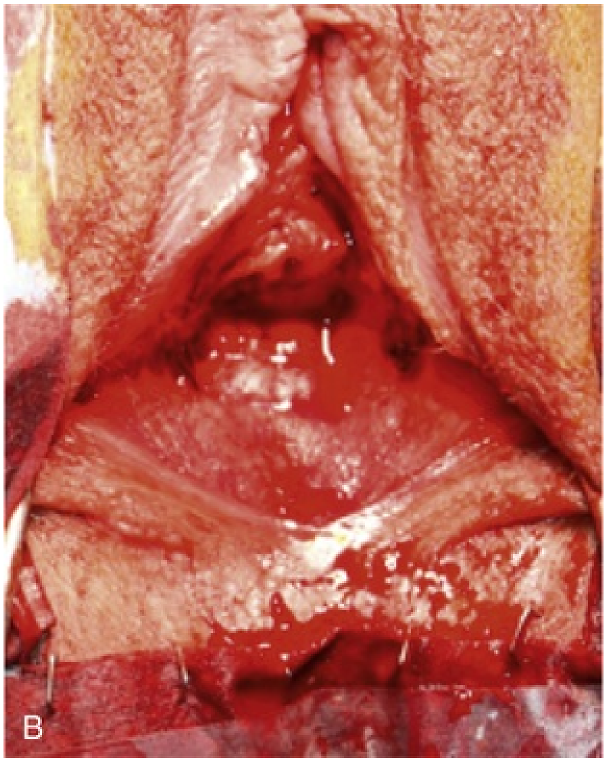


FIG. 134.5 Approximation of the levator muscle. (A) Sutures at the levator muscle. (B) After suturing.

The vaginal introitus is then partially closed from anterior to posterior (Figs. 134.6 and 134.7). A small opening (1-cm diameter) remains for evacuation of vaginal mucus.

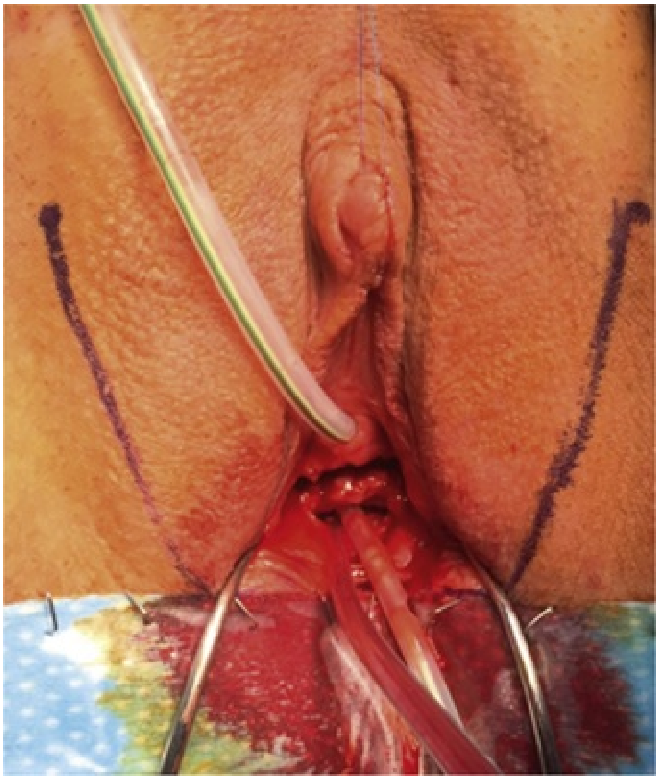

FIG. 134.6 Preservation of the vagina.

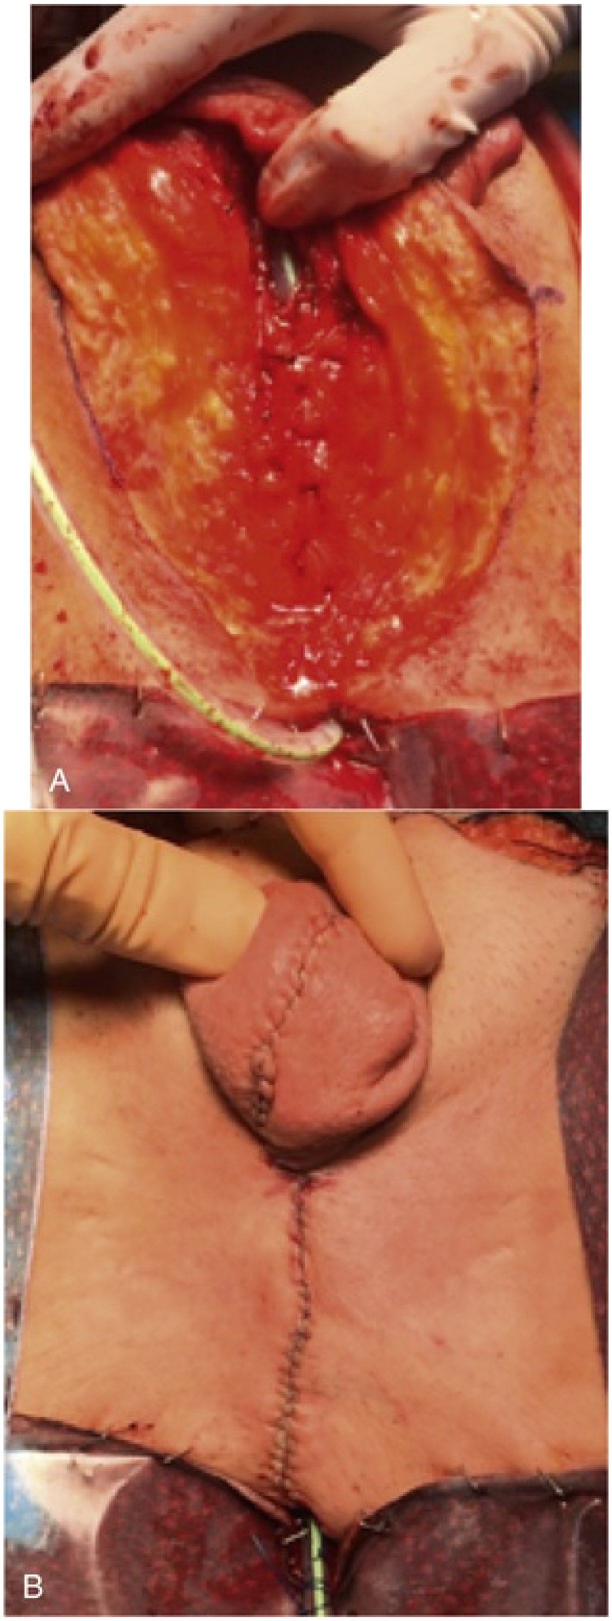

FIG. 134.7 Perineal area in which the vaginal introitus has been partially closed. The drain marks the introitus after creation of the fixed part of the urethra, with approximation of the bulbospongiosus muscle (A) and after

scrotoplasty and closure of the perineum (B).

The best time point to perform vaginectomy remains unclear:

- Vaginectomy can be performed during an “all-in-one” procedure in which full female removal (mastectomy, ovariectomy, hysterectomy, and vaginectomy) is combined with genitoperineal transformation. In the series by Weyers et al. (2010), where phalloplasty was performed, there were more major complications and a higher transfusion rate in case of an all-in-one-procedure. Stojanovic et al. (2017) reported no higher complication rate for the all-in-one-procedure compared with multistage surgery, however, in these series, metoidioplasty was performed instead of phalloplasty.
- Vaginectomy can also be performed at the time of hysterectomy and ovariectomy and combined with temporary metoidioplasty. The phalloplasty is then performed at a later stage. The potential advantage of this is that blood loss and hypotension related to the vaginectomy will not affect perfusion of the phalloplasty as it is not performed at the same time. However, this theoretical advantage needs prospective confirmation.
- The other option is to perform mastectomy, ovariectomy, and hysterectomy first, followed by vaginectomy and genitoperineal transformation in a second stage.

Genitoperineal Transformation

Urethroplasty

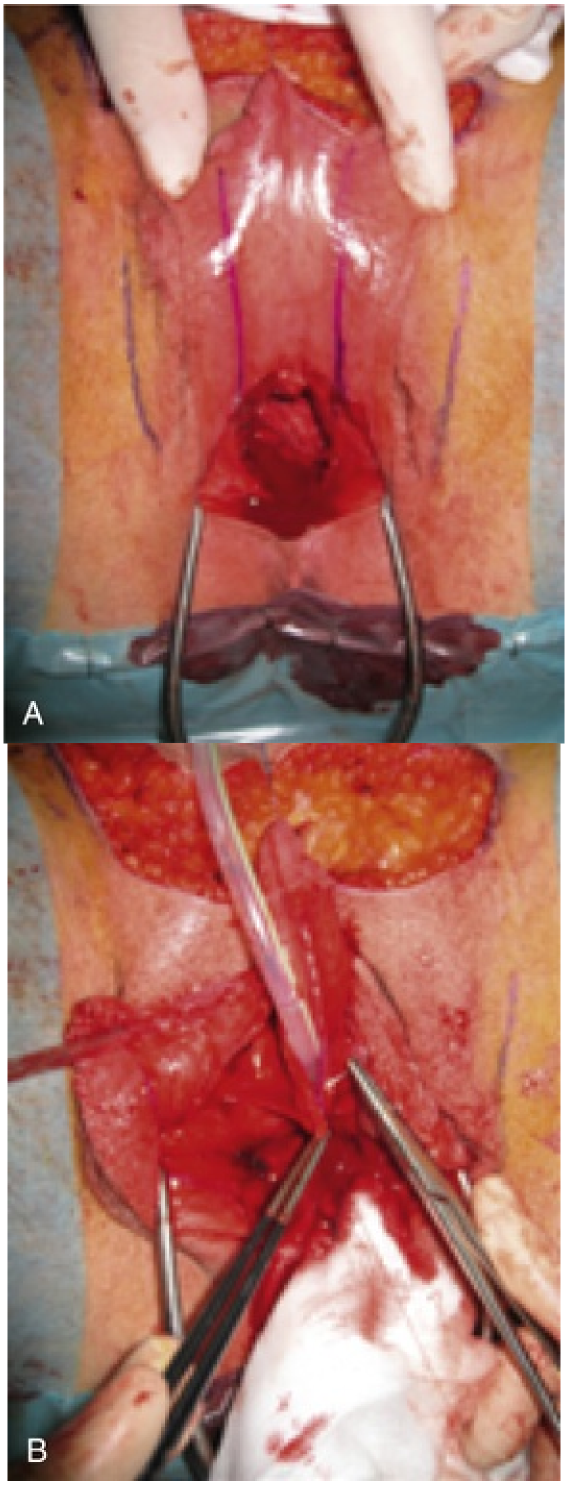
In transmen, the urethra can be divided in **three parts:** the native female urethra, the perineal urethra or fixed part, and the phallic urethra.

- The native urethra: this is the original female urethra from the bladder neck to the external meatal orifice
- The fixed part of the urethra: from the (original female) external

> meatal orifice, the urethra is lengthened under the enlarged clitoris using the vestibular mucosa on the ventral side of the clitoris between the female meatus and the glans clitoris and the inner side of the minor labia, creating a 3-cm-wide urethral plate tubularized around an 18-Fr silicone tube with a running 3.0 polyglactin suture. This fixed part of the urethra is the equivalent of the bulbar part of the urethra in males, however, it will not be surrounded by spongiosal tissue (Kim et al., 2010) (see Fig. 134.4).

Some techniques describe the use of an anterior vaginal mucosa flap to incorporate in the reconstructed urethra. The latter is only possible when performed at the time of vaginectomy (Kim et al., 2010).

After reconstruction of the fixed part of the urethra (Fig. 134.8 and Video 134.1), the mucosa of the clitoral glans is removed. Hydrodissection by submucosal infiltration of diluted xylocaine can aid to this. At this stage, one dorsal clitoral nerve is dissected for 2 to 3 cm. This nerve can be found at the 1 o'clock and 11 o'clock positions. The side of dissection depends on the side of vascular anastomosis of the phalloplasty. A prepubic incision is made at the side of future phalloplasty, and the clitoris is fixed onto the pubic symphysis with a Vicryl 2.0 suture (Fig. 134.9).



A
B

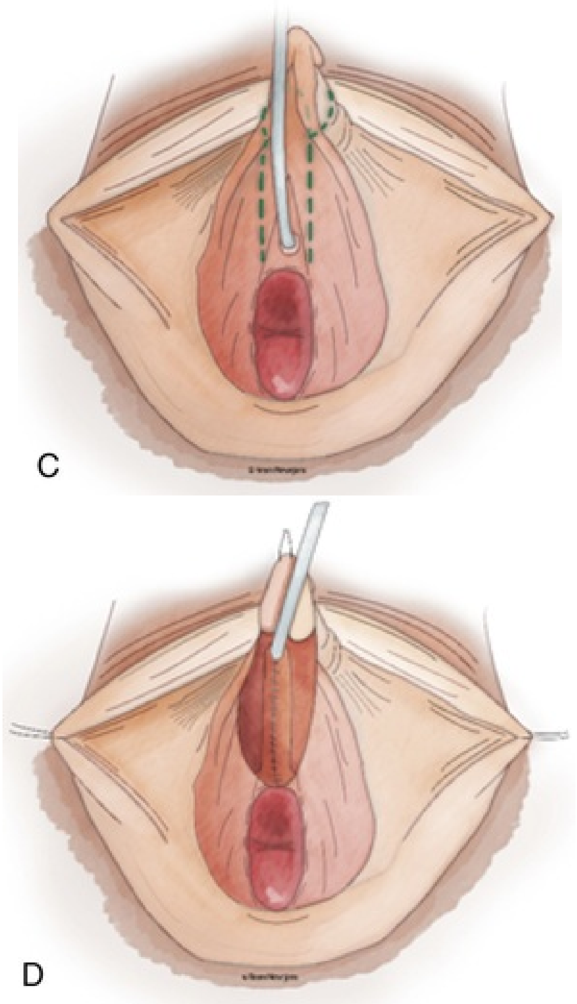


FIG. 134.8 (A to D) Reconstruction of the perineal urethra (pars fixa).

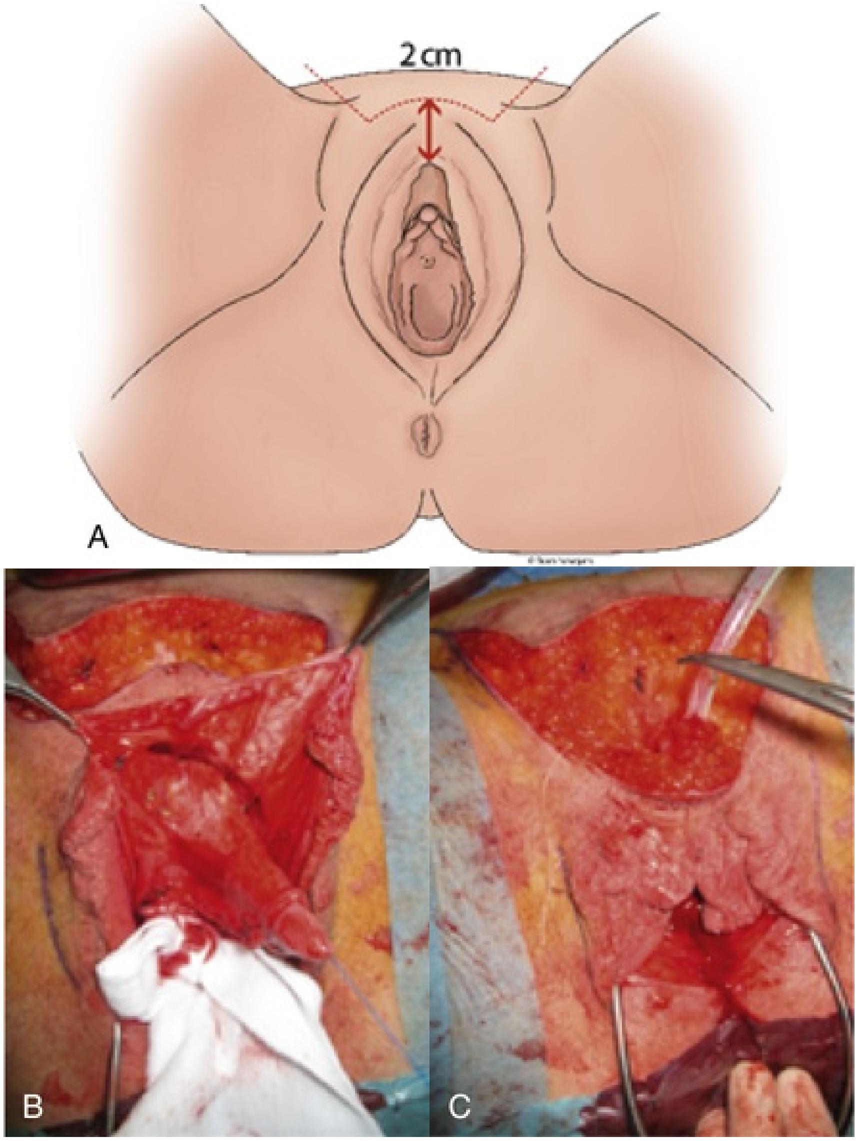

FIG. 134.9 (A to C) Denuding the glans clitoris, dissecting a clitoral nerve, and fixating the clitoris to the pubic bone.

The clitoral nerve will be connected to one of the cutaneous nerves of the flap after the vascular anastomosis has been completed. The distal end of the fixed part is prepared for the future anastomosis with the phallic urethra by placing separate polyglactin 4.0 sutures.

In the perineum, the bulbospongiosus muscles are sutured in the midline to cover the fixed part of the urethra (Fig. 134.10). This will provide a solid vascular support of this part of the urethra (with prevention of fistulae). Furthermore, these muscles can be used to evacuate the last drops of urine that stay in the urethra after micturition. This reduces the embarrassing phenomenon of postvoid dribbling in transmen (Hoebeke et al., 2005).

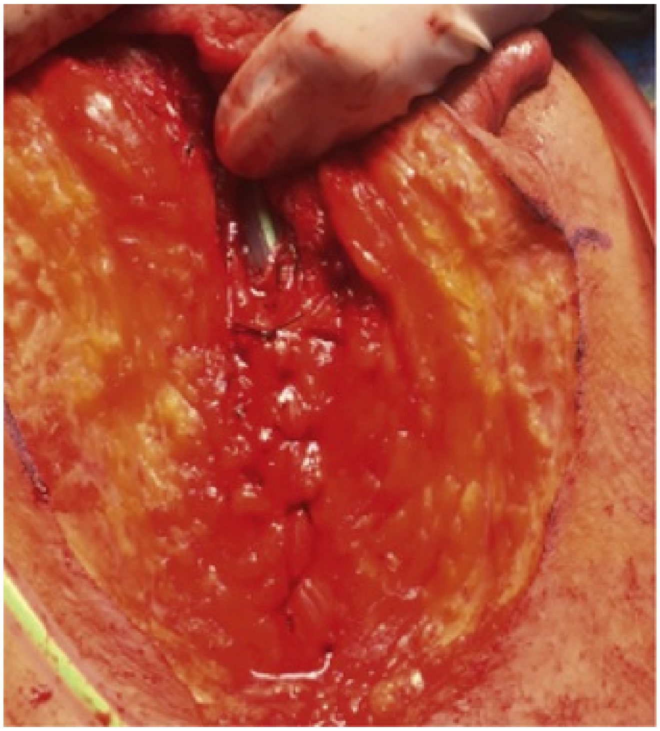

FIG. 134.10 Closure of the bulbospongiosus muscle around the fixed part of the urethra.

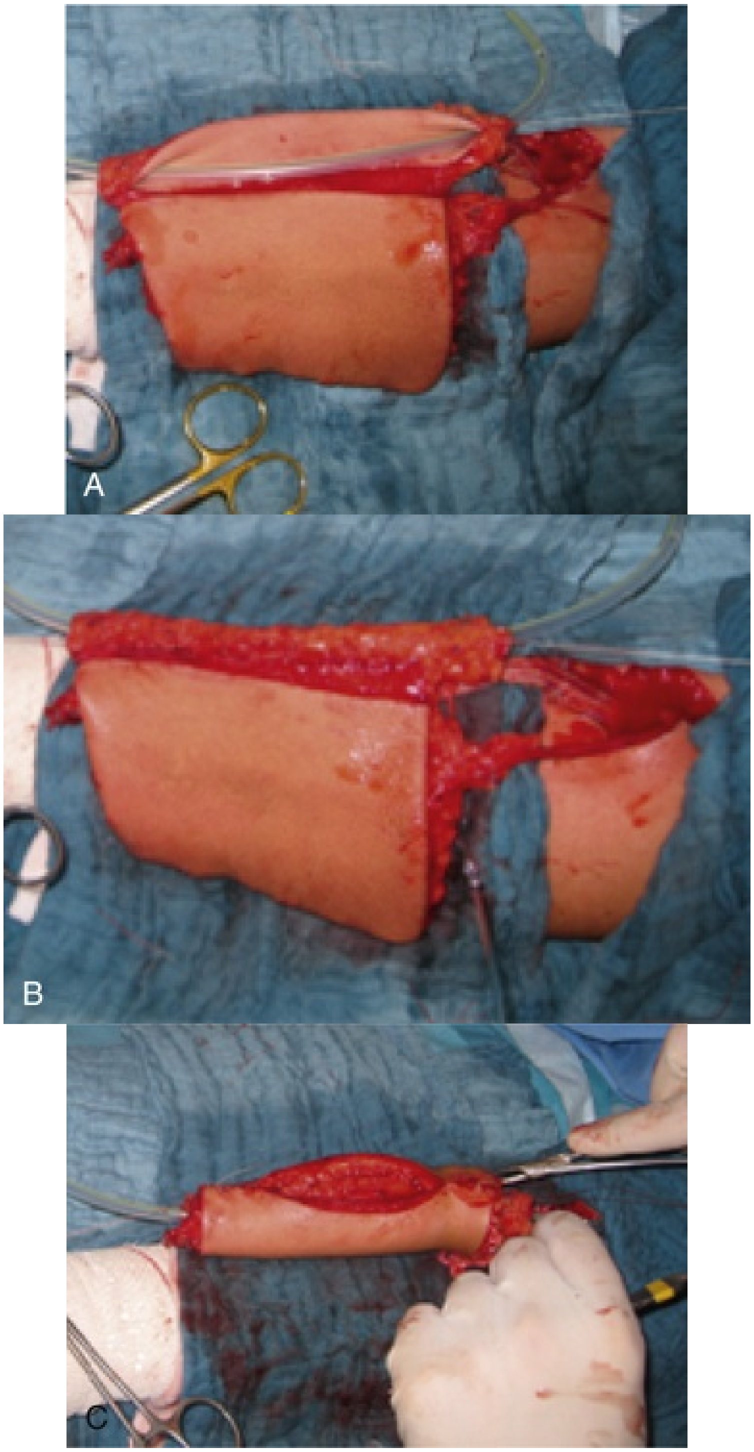
The Phallic Urethra

This part of the urethra is located in the phallic reconstruction and is equivalent to the penile urethra in males but again lacks surrounding spongiosal tissue (Fig. 134.11). The phallic urethra can be made using the tube-in-a-tube principle during phalloplasty. A 3-cm-wide skin island of the flap is wrapped around a catheter and tubularized by a polyglactin 3.0 running suture. The proximal end is connected to the fixed part with the interrupted polyglactin 4.0 sutures that are already in place after the neurovascular anastomosis has been performed (in case of free flap phalloplasty). The distal end is connected to the skin of the phallic reconstruction and will form the neomeatus of the transman. The phallic urethra can also be reconstructed by a separate flap (pedicled or free flap) using the same principles as described for the tube-in-a-tube technique.



A
B
C

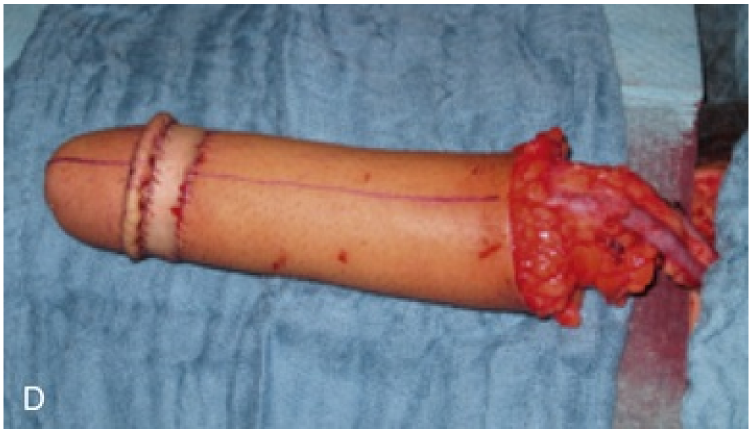


FIG. 134.11 (A to D) Reconstruction of the phallic urethra.

Scrotoplasty

The (hair-bearing) labia majora are used to construct the neoscrotum (Video 134.2▶). Simple midline closure of the labia majora over the former vaginal introitus at the perineum will result in an unaesthetic scrotum that is located between the transman's legs. As the scrotum in males is located in front of the legs, to mimic this, the labia majora are dorsally semi-circumferentially incised and mobilized. This creates bilateral labial flaps supplied by branches of the external pudendal artery. The remnants of the (non–hair-bearing) labia minora and clitoral foreskin are resected from these flaps. The **flaps are turned 180 degrees** and sutured at the top of the perineal skin (Selvaggi et al., 2009). The perineum is closed by subcutaneous polyglactin 1.0 sutures. These large-caliber sutures are needed because there is a lot of tension. The flaps are sutured to each other with resorbable 3.0 sutures. The perineal skin is also closed by resorbable 3.0 sutures (Selvaggi et al., 2009).

Phalloplasty

A **multitude of free and pedicled flaps** are described to reconstruct the phallus. This multitude of flaps indicates that no single flap is able to achieve the ideal goals of phalloplasty. The phalloplasty is done by the plastic surgeon. The choice between different types of flaps depends on the plastic surgeon's expertise, the patient's preference, and, sometimes, local anatomic considerations (e.g., previous surgery in the pelvic or genitoperineal area). Technical details on phalloplasty are beyond the scope of this chapter.

Metoidioplasty

Metoidioplasty is a **potential alternative to phalloplasty** in transmen for whom penetration during sexual intercourse is a secondary or no goal. Metoidioplasty was first described by Lebovic and Laub in 1999 and popularized by Perovic around the same time (Hage and De Graaf, 1993). In this method, a **micropenis** is reconstructed from the enlarged clitoris. With this technique, the fixed part of the urethra is reconstructed as described earlier. However, to lengthen the urethra onto the tip of the clitoral glans, a transverse preputial island flap is used. The neophallus reconstructed by this technique is relatively small (3 to 8 cm) but creates a realistic-appearing penis capable of engorgement with no loss of erotic sensation and, most often, the ability to void standing. There is **most often no ability to penetrate** because of short length, but it is sometimes preferred by transmen because of sexual spontaneity, erection, and sensitivity. Concerns for visible scars in standard phalloplasty may also be at the base of the choice (Monstrey et al., 2008).

Surgically, metoidioplasty relies on straightening of the hypertrophied clitoris by dividing the chordae, releasing the clitoris from the attachments with the labiae minorae, and release of the wide urethral plate on the ventral side by which the clitoris is bent downward. After release of the urethral plate, maximal length can be obtained, but the urethra needs to be lengthened. In our center, we use the transverse preputial island flap to tubularize and use for extension of the urethra.

The **complications** of metoidioplasty can be categorized as minor (Clavien-Dindo grade I and II) or major (Clavien-Dindo III to V). Minor complications such as hematoma, infection, and delayed wound healing do not need surgical reintervention, and major complications including urethral fistulae, urethral stenosis, or flap necrosis need surgical revision. There is only limited experience reported in the literature. Complication rates for minor complications are between 17% and 35%, and major complications account for 7% to 15% of complications (Monstrey et al., 2008; Perovic and Djordjevic, 2003).

Testicular Implants and Erectile Prosthesis

Implantation of testicular and erectile prostheses is done as a **separate procedure. Testicular prostheses can be implanted as early as 6 months after scrotoplasty,** when the scrotum is healed. The size of the scrotum usually allows for the implantation of a 17-mL prostheses. A small incision is made at the base of the scrotum, and a pouch is created bluntly. To avoid displacement, fixation of the prosthesis is advised. Testicular prostheses are usually implanted together with an erectile prosthesis in case the patient also desires the latter.

Implantation of an erectile prosthesis is done as early as 1 year after phalloplasty, if the phallus is endowed with protective sensation and if there are no urethral problems. Although implantation of two cylinders is possible, the bulk of two cylinders can cause ischemia to the skin and the underlying urethra, with an elevated risk for erosion and perforation. One cylinder is usually sufficient to obtain axial rigidity to allow for sexual intercourse. A specific problem in transmen is the lack of a tunica albuginea in which the cylinder can be fixated. For this, the cylinder is fixed at the periosteum of the pubic bone just lateral to the urethra. Malleable and inflatable prostheses are possible in these patients. However, malleable prostheses are technically easier and have a lower risk for technical failure compared with inflatable prostheses. Given the relative hypovascularity of the phallus compared with the native penis and the poor coverage of the prosthesis, **the rate of infection and/or erosion is relative high (20%).** In case of these complications, urgent explantation is needed with subsequent reimplantation at earliest 6 months later. **Technical malfunction (up to 25%) and malposition (up to 15%) are other frequent complications** and reasons for surgical revision (Hoebeke et al., 2003, 2010). Today a specific prosthesis for phalloplasty (ZSI 475 FTM; Zephyr Surgical Implants, Switzerland) has been designed consisting of one larger cylinder with a silicone glans cap and titanium plate at the base that can be sutured to the pubic bone (Fig. 134.12). The implantation technique is shown in ▶Video 134.3.

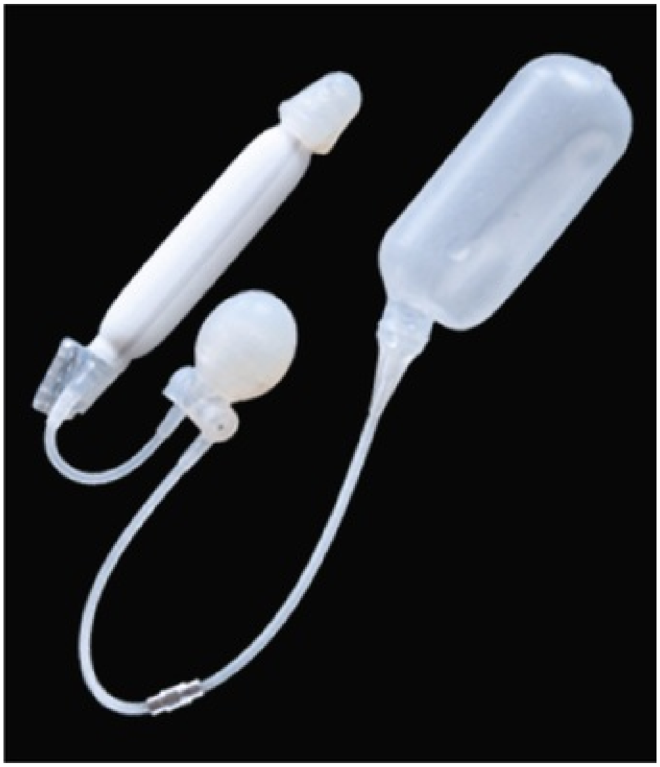

FIG. 134.12 The ZSI 475 FTM inflatable penile implant (Zephyr Surgical Implants, Switzerland).

Postoperative Care, Follow-Up, and Urethral Complications

Early Postoperative Care

Early postoperative care focuses on recovery of micturition after genitourinary reconstruction. In transmen, a suprapubic catheter and a trans-neo-urethral tube are left in situ. After 12 days, the trans-neo-urethral catheter is removed and the patient starts to void. Sometimes, because of significant swelling or a neurogenic impairment to the bladder after vaginectomy, the ability to void and empty completely can be delayed. The suprapubic catheter is then used until normal function is acquired.

In transwomen, a bladder catheter is left in situ for 10 days. After removal, patients usually can void to completion, however, there can be some delay because of neurogenic impairment of bladder function after the creation of the vaginal cavity between the rectum and bladder.

Further early postoperative care is standard as in most urogenital surgical procedures.

Transurethral Catheterization in Transmen

Insertion of a transurethral catheter in transmen is not as easy as in males. The curve toward the native urethra is abrupt, and two small sinuses toward the orifices of Bartholin glands are present bilaterally from this native urethral meatus in which the tip of the catheter can get stuck.

In elective cases, transurethral catheterization must be done by the urologist. One attempt of blind catheterization with a Tiemann tip catheter can be performed, but this attempt must be aborted in case of any problems. A second attempt can be performed with the use of a Freudenberg mandarin by which the sharp curve at the native female urethral meatus can be passed easily. However, in case of any difficulties, it is better to stop and do a flexible cystoscopy with placement of a guidewire into the bladder to avoid provoking urethral trauma (and subsequent stricture formation). An open tip catheter is then placed over this guidewire.

In emergencies, placement of a suprapubic catheter is always a good

solution.

Urethral Complications in Transmen

Up to 40% of patients will suffer urethral complications after phalloplasty.

Urethral Fistula

A urethral fistula is a very common early postoperative complication (35%) (Monstrey et al., 2009). It is related to delayed wound healing of the phallus. The most common location is at the base of the phallus followed by fistulae at the shaft of the phallus. Perineal fistulae are rare because of the better coverage of the urethra with local tissues at this location. However, if vaginectomy has not been performed, urethrovaginal fistulae can arise (Fig. 134.13).

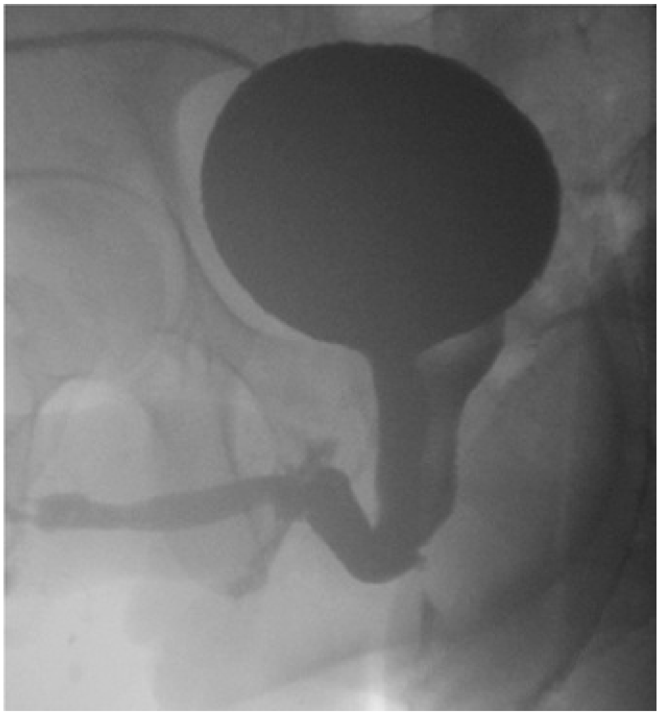

FIG. 134.13 Urethrovaginal fistula on voiding cystography.

In the early postoperative period, the fistula is evident if the urethral catheter is visible through the wound dehiscence. As there is usually an association with delayed healing of the phallus, further maceration of the wound should be avoided. For this purpose, the urinary diversion (transurethral or suprapubic catheter) is maintained until this issue is resolved. After this period, the urinary diversion can be removed, and the patient can start to void through the fistula. **Smaller fistulas have a high chance (up to 70%) of spontaneous closure** (Monstrey et al., 2009). If the fistula persists for longer than 3 months, it is assumed to be permanent, and a surgical closure will be required. The principles of fistula closure must be respected for these patients as well. The fistulous tract is excised with closure of the urethra and skin and with interpositioning of a healthy layer between both. As no dartos layer is available in these patients, only local fatty tissue can be used for coverage. After fistula repair, a catheter is maintained for 10 to 12 days. Compared with the male urethra, which consists of mucosa in spongiosal tissue, the phallic urethra is based on skin from the flap in which healing is delayed.

Urethral Stricture

Incidence.

The risk for urethral stricture is **about 20%** (Monstrey et al., 2009). Again, stricture formation is usually related to healing problems of the phallus and most commonly occurs at areas with a poorer blood supply. This is the reason why the majority of strictures are located at the phallic part of the urethra, the anastomosis, or the external meatus (Lumen et al., 2011). This is a mucocutaneous junction that is prone to stricture formation enforced by delayed healing as a result of poorer blood supply at the extremities of the flap. Most of the strictures at the anastomotic site are short and will usually appear short after phallic reconstruction. Clinical signs and symptoms are the same as in males with urethral stricture.

Diagnosis.

As in males, transmen with urethral stricture will present with a typical plateau curve on uroflowmetry. **Retrograde urethrography (RUG)** is necessary in case of suspicion of urethral stricture. RUG is able to confirm the diagnosis and will provide valuable information about the location and length of the stricture. The three parts of the urethra (the native female urethra, the perineal urethra or fixed part, and the phallic urethra) can be clearly distinguished during RUG (Fig. 134.14). In case of any doubt, urethroscopy can be performed.

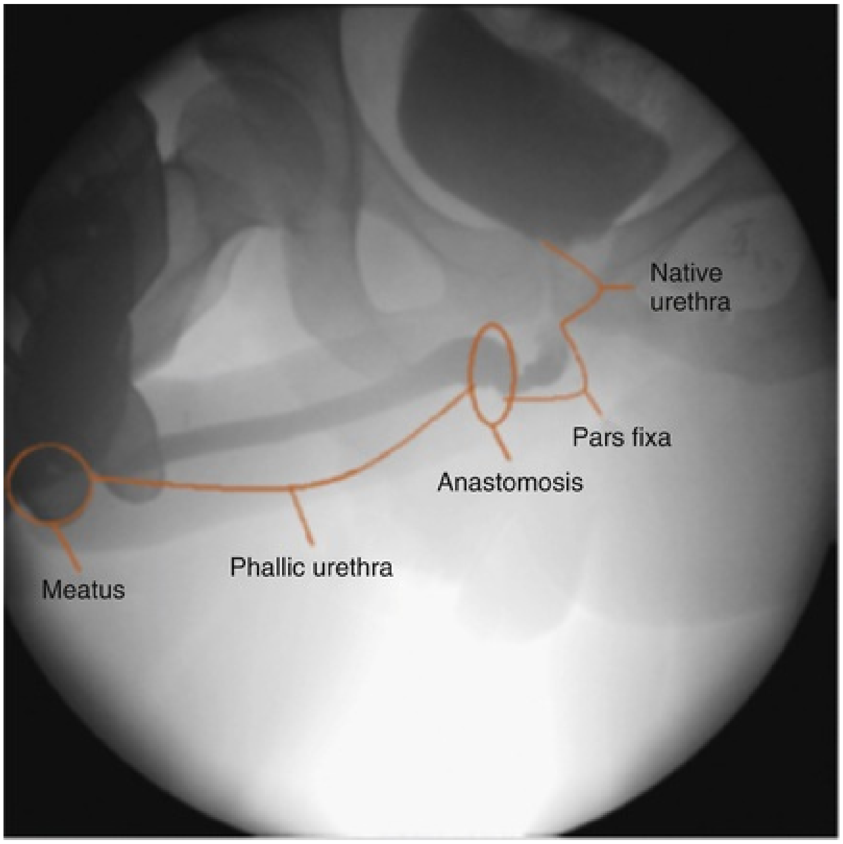

FIG. 134.14 The three parts of the urethra (native female urethra, perineal urethra or fixed part, and phallic urethra) in transmen after phalloplasty as seen on retrograde urethrography.

Management.

Any form of treatment of urethral stricture disease should be **postponed for at least 3 months and preferably 6 months after phallic reconstruction,** at the time wound healing of the phallus has stabilized. It is useless to perform reconstruction during the acute phase of inflammation and wound healing. In case of invalidating obstructive symptoms or retention, a suprapubic catheter is inserted as first-line treatment. A perineostomy is an option if a long interval for definitive urethral reconstruction is expected, in case of severe complaints related to the suprapubic catheter (e.g., bladder spasms), or in case of refusal of the suprapubic catheter. This perineostomy can be closed at the time of urethral reconstruction or in a later phase if the urethral reconstruction appears to be successful.

The type of treatment depends on previous interventions, stricture location, stricture length, and concomitant problems related to the phallus (e.g., flap contracture).

Urethral Dilation

Intermittent urethral dilation is an option for **low-grade meatal stenosis.** The interval of dilation is dictated by the interval of stricture recurrence. A single dilation is possible for a **short flimsy stricture at the anastomosis** between the phallic and fixed part. This dilation is preferably done with fluoroscopic guidance to avoid creating a false passage at the urethra. A guidewire is placed through the stricture, and progressive dilation is performed until it is 18-Fr (if possible). This can be done without anesthesia. **Repetitive dilations for anastomotic strictures are not curative.**

Endoscopic Incision (Direct Vision Internal Urethrotomy)

Endoscopic incision is done under sedation (if the phallus is not sensitive yet) or under spinal/general anesthesia. Again, a guidewire is passed through the stricture to avoid false passage. Direct cold-knife incision at the 4 o'clock, 8 o'clock, and 12 o'clock positions is performed until the underlying fatty tissue is reached and passage of the resectoscope is possible. An 18-Fr transurethral catheter is left in place for 2 weeks. This period is required as it is skin that needs healing and not urethral mucosa, surrounded by spongiosal tissue. **Endoscopic incision has a success rate of 44%. Repetitive endoscopic incisions are of no value.** The sooner after phallic reconstruction, the lower the chance of success (Lumen et al., 2009).

Urethral Reconstruction

Urethral reconstruction is performed for short (<3 cm) strictures refractory to dilation or endoscopic incision and for longer strictures at any segment of the urethra in transmen. Compared with urethral reconstruction in native males, a higher recurrence rate is observed (25% to 61.9%) (Lumen et al., 2011).

Meatotomy

This is indicated for **short meatal strictures** in which dilation is not possible or wanted by the patient. The ventral side of the stenotic meatus in incised until healthy urethra is reached. The skin of the phallus is sutured to the skin of the urethra. The meatus will become slightly hypospadiac with this technique.

Heineke-Mikulicz Urethroplasty

This is an option for **short, nonobliterative strictures** at any segment of the urethra. The urethra is incised longitudinally and closed transversely.

Excision and Primary Anastomosis

This is reserved for **short strictures at the anastomotic site** between the fixed and the phallic part of the urethra. An incision is made at the penoscrotal angle. A metal sound is introduced through the meatus and marks the distal end of the stricture. The urethra is incised ventrally and further opened until healthy proximal urethra at the fixed part is encountered. In case of complete obstruction, the proximal end of the stricture can be marked by passing a metal sound through the perineostomy or the suprapubic tract. The stenotic segment is completely resected, and both urethral ends are spatulated. Both ends are mobilized to allow for a tension-free anastomosis.

Free Graft Urethroplasty

This is of limited value in transmen. The phallic urethra is only surrounded by fatty tissue and does not sufficiently support a graft. The results are, as a consequence, disappointing. At the fixed part, a graft can be placed after incision of the urethral plate as a dorsal inlay procedure. The graft is quilted against the corporal body of the clitoris. The need for this technique is, however, exceptional seen the low incidence of stricture at this site.

Two-Stage Urethroplasty

This is a **standard technique to treat longer strictures** at the phallic urethra. The urethra is opened, and marsupialization is obtained by suturing the borders of the urethra to the borders of the skin incision. In case of a narrow and/or severely scarred urethral plate, the plate can be resected and replaced or augmented by a full-thickness skin graft or by oral mucosa. At least 3 months later, if the urethral plate has healed well, the borders of the marsupialized urethra are incised and retubularized around a urethral catheter.

Flap Urethroplasty

Substitution urethroplasty with local phallic or scrotal skin flaps is of limited use seen the paucity of mobile local tissues and the risk for penile/scrotal deformities after local flap harvest. **For complex or recurrent stricture at the phallic urethra, a complete urethral substitution at this part needs to be performed.** Options are a radial forearm free flap or a superficial circumflex iliac artery free or pedicled groin flap. Other problems at the phallus (e.g., graft contracture) can be managed at the same time with additional grafting or flap procedures.

Definitive Perineostomy

The technique is the same as for contemporary perineostomy in the early postoperative phase. The perineum is incised at the midline until the fixed part of the urethra is reached. The fixed part of the urethra is opened longitudinally over 4 to 5 cm. The borders of the urethra are sutured to the borders of the perineal skin. This is an option for patients with refractory urethral strictures who do not wish further urethral reconstruction (Fig. 134.15).

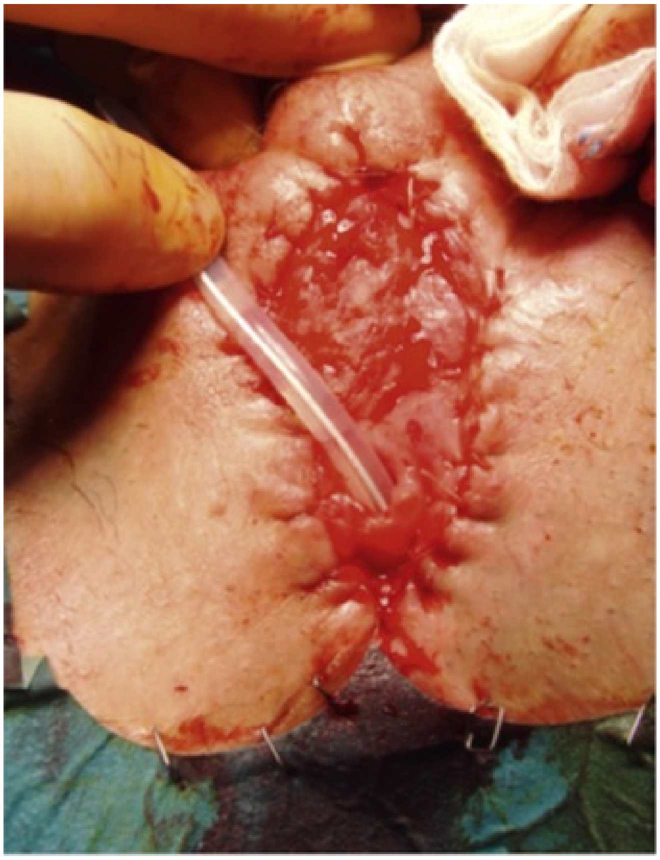

FIG. 134.15 Contemporary perineostomy.

Urethral Hair Growth

In case the urethra is made from skin flaps (which is usually the case), hair growth can occur in the urethra. This is usually without any consequences. Prevention is of utmost importance. If a skin flap will be used for the phallic urethra, a flap from a region with no or minimal hair growth is harvested (e.g., ulnar side in case of radial forearm flap). If this is not possible, preoperative laser epilation is strongly recommended.

In case of substantial hair growth, a hairball with stone formation is possible. Related symptoms are difficulty voiding, local irritation, and urethral discharge. Once it has formed, the phallic urethra is opened at the ventral side with removal of the stone (if present). The borders of the urethra are sutured to the borders of opened skin of the phallus. The hairs at the urethra can be treated subsequently with **laser epilation.** In the next stage, the urethral plate is tubularized as during the second stage of a two-stage urethroplasty.

Postvoid Dribbling

Nearly all transmen will experience some form of postvoid dribbling (Hoebeke et al., 2005). The urethra in transmen is merely a rigid tube as it lacks the elasticity from the surrounding spongiosus tissue in males. Furthermore, although reconstruction of the bulbospongiosus muscle is performed during phalloplasty (see earlier), this reconstructed muscle is not as effective to squeeze out the last drips of urine at the end of micturition. **Perineal pressure at the end of micturition combined with squeezing of the phallus** is an option in case of bothersome postvoid dribbling. In case of severe postvoid dribbling, urethrography or urethroscopy must be performed to exclude urethral sacculation or a pseudodiverticulum from a vaginal remnant. If this is the case, resection might resolve or at least reduce the problem.

Conclusion

Despite the fact that SRS is only carried out in a few specialized centers, the number of people who have undergone SRS is considerable. They can present themselves to each urologist with urologic problems, which is why insight into the reconstructive techniques and possible complications is useful for every urologist. The aim of this chapter was to provide any urologist with essential knowledge to be able to take care of acute urologic problems. Thereafter, referral to experienced centers for treatment of the complications is advisable.

Key Points

- The urologist has an important role in the treatment and follow-up of transgender individuals.
- Urinary incontinence is the most frequent complication in transwomen.
- It is important to be aware of prostate pathology in transwomen.
- Whether or not to perform vaginectomy in transmen should be discussed with the patient.
- Urethral fistula and stricture are frequent complications in transmen and most often occur at the anastomosis between the fixed part and phallic part of the urethra.
- Metoidioplasty is an alternative to phalloplasty in transmen who refuse to accept the complications of phalloplasty.
- Implantation of an erectile prosthesis in transmen is associated with a higher risk for complications compared with native males.

Tumors of the Bladder

Max Kates MD, Trinity J. Bivalacqua MD, PhD

Epidemiology

Incidence, Prevalence, Mortality

Bladder cancer is a global disease, with 540,000 incident cases and 188,000 deaths in 2015 worldwide (Fig. 135.1). In the United States 81,190 patients will be diagnosed in 2018 and 17,240 will die from their disease (American Cancer Society, 2017). Although age-adjusted incidence and mortality rates initially declined in the 1990s and early part of 2000s, these rates have plateaued in recent years (Dy et al., 2017; Ferlay et al., 2014). Between 2005 and 2015 unadjusted incidence rates of bladder cancer grew 31%, which has been attributed to aging and population growth (Fitzmaurice et al., 2017). This increase in incidence has been attributed to the increase in life expectancy over time and the resultant aging of the global population. Adjusted for demographic changes, the incidence rates for bladder cancer have remained relatively stable (Fig. 135.2). The United States has seen a decline in incidence rates from 2005 to 2014 by 0.8% per year in men and women (American Cancer Society, 2017). The odds of developing bladder cancer are highest in high-income countries (1 in 36 men and 1 in 165 women) and lowest in low-income countries (1 in 122 men and 1 in 310 women). In 2015 age-specific incidence rates were highest in North American (31.6 per 100,000), Western Europe (26.0), and Central Europe (24.1), and lowest in Oceania (4.5), Andean Latin America (5.8), and Central Latin America (5.9). However, since 1990, developing countries have had an increasing burden of bladder cancer incidence compared with developed countries, which has been attributed to a narrowing gap in life expectancy between low- and high-income countries, with subsequent higher rates of cancer in an older population (Dy et al., 2017).

FIG. 135.1 Global incidence rates of bladder cancer. (Data from Ferlay J, Soerjomataram I, Ervik M, et al.: GLOBOCAN 2012 v1.1, Cancer incidence and mortality worldwide: IARC CancerBase No. 11. Lyon, *Fr. Int Agency Res Cancer,* 2014 [website]: http://globocan.iarc.fr)

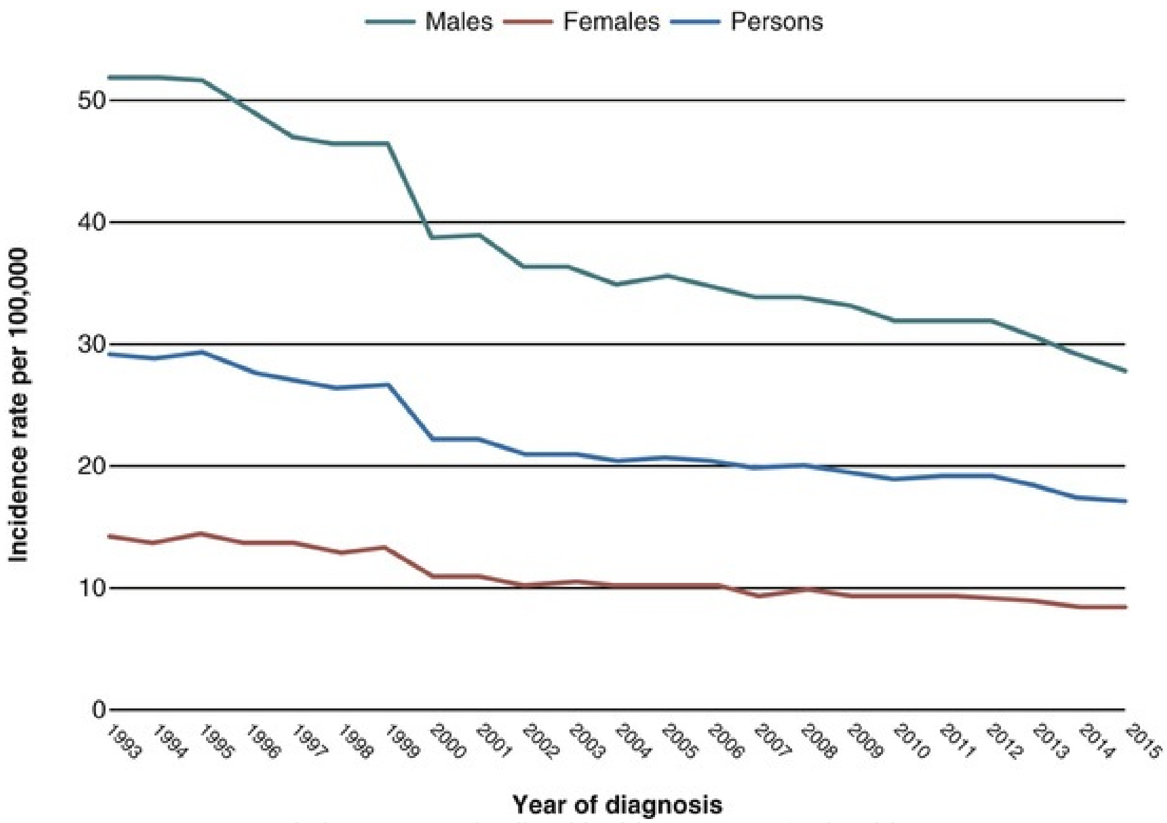

FIG. 135.2 Trends in age-standardized incidence rates for bladder cancer, 1993 to 2015. (Modified from Cancer Center UK: *Bladder cancer statistics,* 2018 [website]: https://www.cancerresearchuk.org/health-professional/cancer-statistics/statistics-by-cancer-type/bladder-cancer.)

Although incidence rates are highest in Europe and North America, more than 60% of all bladder cancer incidence, and nearly half of bladder cancer deaths occur in the developing world (Antoni et al., 2017). Disability-adjusted life-years (DALYs) are the primary way in which the World Health Organization (WHO) quantifies the burden of disease from mortality and morbidity. DALYs correspond to the years of life lost (number of deaths × remaining life expectancy) and the years lost because of disability. Bladder cancer causes approximately 3.4 million DALYs in 2015. Furthermore, although age-standardized DALYs rates for bladder cancer among both sexes decreased by 9%, incidence rates have remained steady among high-income countries.

Because bladder cancer has fewer deaths relative to incident cases compared with several other malignancies, bladder cancer is one of the world's most prevalent cancers. The global 5-year prevalence of bladder cancer is estimated to be 1,319,749, with 243,867 coming from the United States (Ferlay et al., 2014). However, 5-year prevalence may not fully reflect the number of bladder cancer survivors managing disease sequel, as an estimated 571,518 bladder cancer survivors lived in the United States in 2011 (Malats and Real, 2015). Among cancers affecting both sexes, bladder cancer ranks as the fourth most prevalent cancer globally, and in the top 5 in prevalence in individual countries of all income levels and all regions, including the United States (96.6 patients per 100,000), Argentina (32.6), Egypt (41.2), Belgium (158.6), Australia (59.7), and Japan (71.0) (Bray et al., 2013; Ferlay et al., 2014; see Fig. 135.2). Regional variations do exist, however. Bladder cancer was the most commonly diagnosed cancer in 2015 for men in Egypt primarily because of high rates of *Schistosoma haematobium* in that country, which causes squamous cell carcinoma (SCC) of the bladder. In Europe, the highest world age-standardized incidence rates for bladder cancer are in Belgium for men and Hungary for women (Ferlay et al., 2014, 2013). These regional differences are due to a combination of factors, including a country's demographic characteristics and environmental exposures.

Gender, Racial, and Age Differences

Bladder cancer typically arises from chronic, constant insults to the urinary tract over time. Urothelial cancer is a disease of aging and environmental exposures. As such, the incidence and prevalence increase with age. The average age of diagnosis is 73 in the United States with approximately 9 of 10 patients diagnosed after the age of 55. Age-specific incidence rates rise gradually around age 50 to 54 in males and females, with a sharper rise in males age 60 to 64. The highest age-adjusted incidence rates are in the 90+ age group for both sexes (Fig. 135.3).

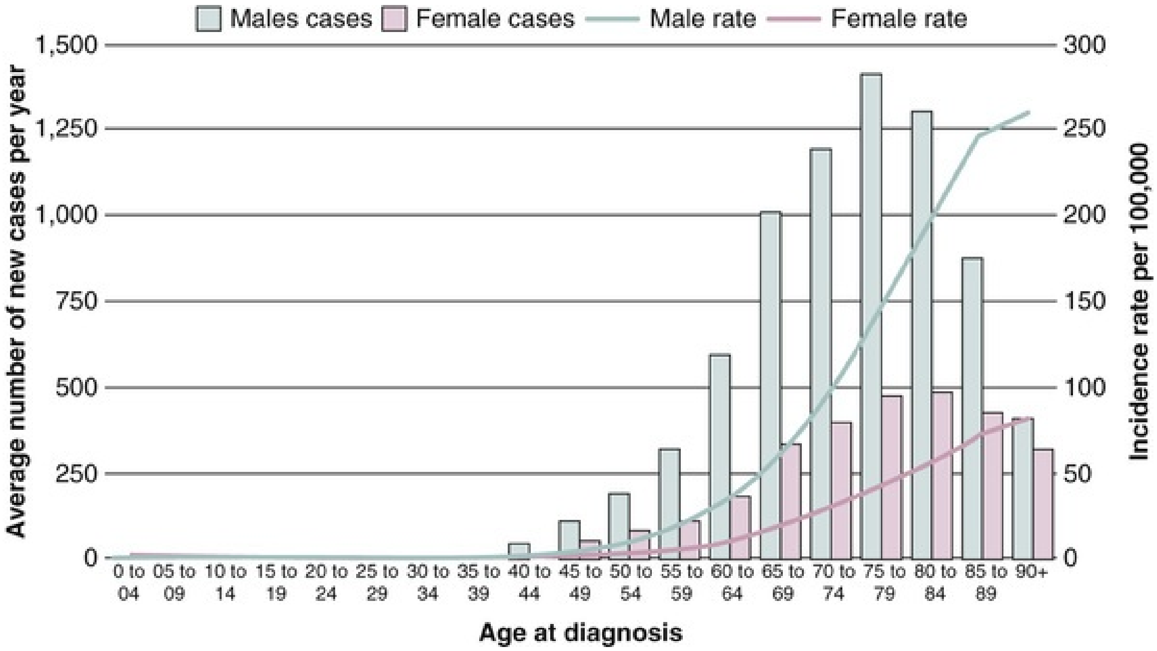

FIG. 135.3 Age-adjusted incidence rates for bladder cancer in the United Kingdom. (Data from Cancer Research UK: *Cancer stats,* 2017 [website]: https://www.cancerresearchuk.org/cancerstats.)

Nearly three-quarters of bladder cancer cases occur in males, who have a higher incidence rate (9.0 per 100,000) compared with women (2.2). In the United States, 1 in 27 men will develop bladder cancer over their lifetime, and 1 in 107 US men will die of bladder cancer. For women, 1 in 89 US women will develop bladder cancer, and 1 in 293 will die of their disease (American Cancer Society, 2017). Several hypotheses have been proposed for increased bladder cancer rates among men. First, globally smoking is much more common in men in comparison with women, with age-standardized prevalence declining in men from 41.2% in 1980 to 31.1% in 2012 in comparison with 10.6% to 6.2% among women (Chappidi et al., 2017). However, even when controlling for smoking, gender-related incidence disparities persist (Hartge et al., 1990). It has been hypothesized that although carcinogen exposure may not account for differences between genders, cellular metabolism of carcinogens may be different (Hemelt et al., 2009). Metabolic enzymes including 5′-diphosphoglucuronosyltransferase (UGT), which is involved in aromatic amine metabolism, and glutathione-*S*-transferase M1 (GSTM1), involved in foreign substance detoxification, have been implicated in bladder cancer–associated carcinogen metabolism. Both enzymes have been shown to be differentially expressed in men and women (Karagas et al., 2005; Zhang, 2013). As a result, gender differences in carcinogen metabolism may explain why even among similar carcinogen exposures (e.g., similar smoking pack-years), gender disparities in bladder cancer incidence persist.

In addition, gender differences have been explained by differences in sex steroid production and receptor expression. Among women, older age at menarche (≥15), parity (compared with nulliparous women), and use of estrogen or progestin therapy have been associated with decreased UCB risk, suggesting that sex steroid exposure mitigates bladder cancer risk (Daugherty et al., 2013). From a tumor biology standpoint, the androgen receptor (AR) has been implicated in bladder cancer development and progression. AR expression appears to be downregulated in immunohistochemical studies of bladder cancer, and this downregulation appears to increase with higher stage/grade tumors (Li et al., 2017). Transgenic and N-butyl-N-(4-hydroxybutyl)-nitrosamine (BBN) mouse models of bladder cancer have demonstrated that castration or direct AR knockout suppresses bladder cancer growth and development (Johnson et al., 2008; Miyamoto et al., 2007).

Although the disease is more prevalent in men, women are more likely to have more advanced tumors and a less-favorable prognosis (Scosyrev et al., 2009). Although men lose 26% of their remaining life expectancy to bladder cancer, women lose 36% (Scosyrev et al., 2012). The differences in stage presentation only account for approximately 30% of gender disparities in bladder cancer prognosis and mortality; women fare worse than men stage for stage (Aydin Mungan et al., 2000; Scosyrev et al., 2009). This gender disparity in the aggressiveness of bladder cancer at presentation has been attributed to differences in tumor biology, environmental exposures, and as well as implicit bias (also known as implicit social cognition), in which the conception of bladder cancer as a “male” disease leads to delays in diagnosis from initial hematuria symptoms to pathological diagnoses. Multiple series using insurance claims data have demonstrated that women have a delay from their initial hematuria claim to their bladder cancer claim compared with men and that women are more likely to be referred for urinary tract infection (UTI) evaluation and therefore have a delay in referral to a urologist (Buteau et al., 2014; Cohn et al., 2014; Garg et al., 2014). These delays in diagnosis may partially explain why women are more likely to present with advanced stage disease.

Bladder cancer is most common among Caucasian Americans, with an incidence rate 1.5 times that of African-Americans, twice that of Hispanic Americans, and six times that of Native Americans. However, similar to gender differences, African-American patients are more likely to have muscle-invasive disease compared with Caucasian patients (Scosyrev et al., 2009; Fig. 135.4). In addition, for reasons that are unclear, African-Americans, and African-American women in particular, have increased rates of non-urothelial histology. Rates of non-urothelial histology among African-American women (10.5%) are greater than African-American men (5.9%), Caucasian American men (2.3%), or Caucasian American women (4.3%) (Scosyrev et al., 2009). Stage for stage, 5-year relative survival rates are worse for African-Americans with localized disease (61% vs. 70%) and regionally advanced disease (28% vs. 36%) compared with all Americans (Siegel et al., 2018).

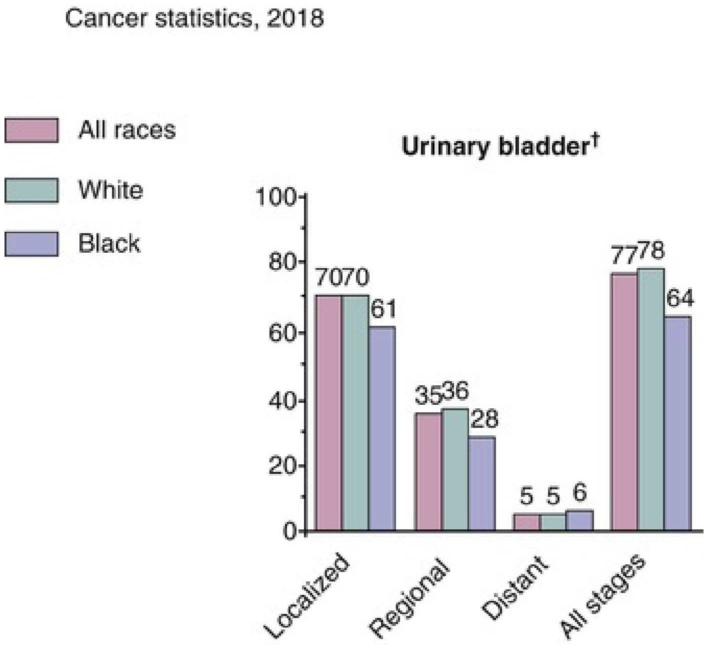

FIG. 135.4 Five-year relative survival rates for selected cancers by race and stage at diagnosis, United States, 2007 to 2013. The standard error is between 5 and 10 percentage points. †The survival rate for carcinoma in situ of the urinary bladder is 96% in all races, 96% in whites, and 91% in blacks. (Data from Siegel RL, Miller KD, Jemal A: Cancer statistics, 2018. *CA Cancer J Clin* 68:7–30, 2018.)

Economic Impact

Bladder cancer is the most expensive cancer to treat per patient over a patient's lifetime (Curtis, 2016). The lifetime treatment cost per patient is between $129,000 to $251,000. Annual directed medical costs are estimated to exceed $4 billion in the United States and €4.9 billion in the European Union (EU) (Curtis, 2016; Leal et al., 2016). However, bladder cancer health care costs vary widely between countries and disease states. For example in Latvia €2257 is spent per bladder cancer case compared with €11 937 in France (Leal et al., 2016). Europe as a whole spends €45 per 10 EU citizens compared with €97 per 10 US citizens. These variations between countries and between patients in the same country can be attributed to regional variations in the management of bladder cancer, particularly non–muscle-invasive disease. In addition, treatment costs vary by institution and region (Svatek et al., 2014). Two areas that have been proposed for future research and interventions to improve bladder cancer costs are in the management of patients with non–muscle-invasive bladder cancer (NMIBC) in whom intense surveillance strategies often lead to procedures and laboratory testing annually, and in patients with metastatic disease resulting from large costs of late-stage therapeutics and end-of-life care (Svatek et al., 2014).

Risk Factors

Like skin and lungs, the bladder is an organ that comes in constant contact with the environment and is therefore sensitive to environmental carcinogens and inflammation. Aromatic amines (2-naphthylamine, 4-aminobiphenyl, and benzidine) are thought to be the central causative agent in carcinogen-mediated bladder carcinogenesis. Tobacco smoking and occupation account for the two most frequent routes of environmental exposure. Tobacco smoke is full of aromatic amines, as are other environmental carcinogens implicated in bladder cancer. These amines, when hydroxylated, lead to DNA adduction and damage.

Genetics

The most-studied genes associated with bladder cancer are *N*-acetyltransferase 2 (NAT2) and a deletion of glutathione S-transferase μ (GSTM1) (Garcia-Closas et al., 2005; Golka et al., 1997; Karagas et al., 2005). Both of these genes are associated with the ability to metabolize aromatic amines and thus play an important role in the subset of individuals with environmental carcinogen exposure. NAT2 detoxifies nitrosamines, regulating the rate of acetylation of aromatic amine compounds found in cigarette smoke (Garcia-Closas et al., 2005). Recent evidence suggests that there are likely several underlying genetic risk factors, that when combined with occupational, environmental, and behavioral exposures, potentiate bladder cancer risk and development (Czerniak et al., 2016).

Hereditary

Although first-degree relatives of patients with bladder cancer have a twofold increased risk of developing urothelial bladder cancer, high-risk bladder cancer families are exceedingly rare. Hereditary bladder cancer does not seem to be associated with a Mendelian inheritance pattern, making classical family-tree linkage studies unhelpful. More likely the cause is multifactorial, in which certain genes magnify environmental exposures (Kiemeney, 2008). Patients with Lynch syndrome (hereditary non-polyposis colon carcinoma, HNPCC) are at increased risk of developing urothelial cancer. This increased risk is primarily found among the mismatch repair gene *MSH2* mutations carriers (van der Post et

al., 2010).

Smoking

Tobacco is the main known cause of bladder cancer and accounts for 30% to 40% of all urothelial carcinoma. Worldwide there are more than 1 billion current smokers, and smokers have a 2- to 3-fold increased risk of bladder cancer (Islami et al., 2015). Although cigarette smoking is the most common tobacco product associated with bladder cancer risk, pipe smoking and cigar smoking have also been associated with urothelial carcinoma formation (Cumberbatch et al., 2016). Current cigarette smoking among US adults declined from 20.9% (45.1 million US adults) in 2005 to 15.1% (36.5 million) in 2015. This represents a 27.7% decline in a 10-year period (Jamal et al., 2016). Aromatic amines are the primary carcinogens in tobacco smoke that lead to cancer. Persons with *NAT2* slow acetylation polymorphisms have been shown to be at a particularly high risk when they smoke cigarettes, because *NAT2* allows for the detoxification of these amines. Although there is some evidence that dietary beta-carotene may have protective effects, supplementary beta-carotene and vitamin supplementation (with C, E, or folate) have not been shown to mitigate bladder cancer risk among those with environmental exposures (Roswall et al., 2009). Smoking cessation has been shown to decrease the risk of urothelial cancer formation: smokers who have stopped for 1 to 3 years have a 2.6 relative risk compared with a 1.1 relative risk among those who have stopped smoking for more than 15 years (Koshiaris et al., 2017). Approximately 20% of patients with bladder cancer are smokers at the time of diagnosis, and these patients have an increased risk for local recurrence when actively smoking with NMIBC and increased risk of bladder cancer death when actively smoking with muscle-invasive bladder cancer (MIBC). In addition, many patients with smoking-related cancer continue to smoke even after their bladder cancer is discovered (Koshiaris et al., 2017). The survival benefit of quitting early after a bladder cancer diagnosis is controversial and still an area of active investigation. However, continued smoking increases the risk of a second primary cancer and the risk of other smoking-related diseases, including peripheral vascular disease and chronic obstructive pulmonary disorder (Health NC, 2014).

Body Mass Index

Increased body mass index (BMI) has been shown to be a risk factor for multiple cancers. Increasing BMI has been shown in multiple meta-analyses to be a risk factor for bladder cancer development (Choi et al., 2018; Koebnick et al., 2008; Sun et al., 2015; Zhao et al., 2017). One reason for this link is the strong association between smoking and obesity; however, BMI remains associated with bladder cancer even after controlling for smoking status. There is also a dose-response relationship in which bladder cancer risk appears to increase with BMI. Furthermore, among patients already diagnosed with bladder cancer, obesity appears to attenuate prognosis and is associated with an increased risk of tumor recurrence and a shorter time interval to recurrence (Wyszynski et al., 2014). The mechanism of excess weight contributing to cancer risk includes insulin resistance, chronic hyperinsulinemia, increased bioavailability of steroid hormones, and localized inflammation. Elevated insulin production may drive tumor growth and stimulate pro-inflammatory cytokines. The exact mechanism by which excess weight may contribute to bladder cancer risk is unknown and likely includes a multitude of inflammatory mediators.

Occupational Risk

Occupational exposures account for between 5% and 10% of all bladder cancer (Cumberbatch et al., 2015; Rushton et al., 2010; Table 135.1). Occupations that work directly with chemicals and dyes have the greatest lifetime risk. Particularly at-risk occupations that work with aromatic amines include tobacco, dye, and rubber workers, hairdressers, painters, and leather workers. Those that works with polycyclic aromatic hydrocarbons are also at risk, including chimney sweeps, nurses, waiters, alumni workers, petroleum workers, and seamen (Cumberbatch et al., 2015). Many of these professions are increasingly women, and it has been reported that occupational exposures may be increasing among women in particular.

TABLE 135.1

Relative Risk of Bladder Cancer by Occupation

OCCUPATION	RELATIVE RISK
Tobacco workers	1.72
Dye workers	1.58
Chimney sweeps	1.53
Nurses	1.49

Rubber workers	1.49
Waiters	1.43
Aluminum workers	1.41
Hairdressers	1.32
Plumbers	1.2
Metal workers	1.14
Fishermen	1.13
Physicians	1.11
Mechanics	1.11

Data from Cumberbatch MG, Cox A, Teare D, et al.: Contemporary occupational carcinogen exposure and bladder cancer: a systematic review and meta-analysis. *J Am Med Assoc Oncol* 1(9):1282–1290, 2015.

Medical Conditions

Medical conditions have the potential to increase bladder cancer risk directly or indirectly as a toxicity of treatment. Typically, direct carcinogenesis is mediated by chronic inflammation and the development of keratinizing squamous metaplasia. For example, patients with neurogenic bladder and spinal cord injuries who have chronic indwelling catheters are at a modestly increased risk of developing SCC of the bladder.

Bladder calculi, urinary outflow obstruction, recurrent UTIs, and inflammation from direct catheter trauma have been postulated to be additive in the development of keratinizing squamous metaplasia (Ho et al., 2015; West et al., 1999). In addition, the malignant potential of bladder exstrophy has been well documented, with the reported incidence of 3.3% to 7.5% of the general exstrophy population—several times higher than age-matched controls in the general population (Rieder et al., 2006; Smeulders and Woodhouse, 2001). Adenocarcinoma accounts for more than 90% of cases and squamous cell and urothelial carcinoma account for the remaining 10%. As patients with spinal cord injuries and congenital bladder abnormalities continue to live longer lives because of advances in the care of these individuals, rates of bladder cancer may rise as these patients age.

Schistosomiasis

Schistosomiasis is an infectious disease endemic in as many as 76 developing countries and affecting up to 218 million people (Word Health Organization, 2017). Despite widespread WHO-led eradication campaigns, schistosomiasis remains a major contributor to disease and bladder cancer in many tropical countries. Schistosomes are parasitic blood flukes that have mammalian hosts as well as intermediate hosts (e.g., freshwater snails). Of the four human schistosomes, *S. haematobium* is the one linked to squamous cell bladder cancer. *S. haematobium* live in the venules of the human urinary bladder, where they lay eggs, producing irritation and tissue fibrosis. The mechanism of SCC development likely involves a TH-2 type pro-inflammatory immune response (Bernardo et al., 2016). In addition, underlying *S. haematobium* infection seems to promote susceptibility to other bladder cancer risk factors—notably smoking.

Recurrent Infection

Multiple investigators have suggested that persistent or recurrent bacterial UTIs may increase the risk of bladder carcinogenesis. Multiple epidemiologic studies suggest that there may be a modest, increased risk of bladder cancer associated with chronic UTIs; however, these studies are confounded by chronic intermittent catheterization, chronic inflammatory bladder stone formation, and other risk factors including smoking status and occupational status (Jiang et al., 2009; Vermeulen et al., 2015). In addition, previous gonorrhea infections have been associated with bladder cancer formation. One prospective study found a nearly twofold relative risk of bladder cancer formation in men with a history of gonorrhea, and these tumors are more likely to be invasive (Michaud et al., 2007). The mechanism of action may be related to the production of carcinogens such as nitrosamines that can produce chronic UTIs. However, there have been no prospective studies examining the association between UTIs and bladder cancer risk, and much of the early data demonstrating a connection have not been validated in more contemporary cohorts. Furthermore, recent explorations into the microbiome of the urinary tract suggest that in some instances certain bacterial and viral colonization of the bladder epithelium have a protective effect against tumor formation. Host microbiota have been shown to be crucial to maintaining homeostasis in mucosal surfaces, including the gut and oral cavity; current efforts are underway to define these mechanisms in the bladder (Whiteside et al., 2015).

Indirect Medical Risk Factors

Indirect medical causes of bladder cancer are typically unintended side effects of treatment.

Pioglitazone

Pioglitazone is an antidiabetic drug in the thiazolidinedione class of drugs that lower glucose levels among patients with non–insulin-dependent diabetes. In 2005 the PROactive randomized trial reported an unexpected finding that the pioglitazone arm had higher cases of bladder cancer compared with placebo. These findings were controversial and were subsequently confirmed in some follow-up studies and refuted in others (Boice et al., 1985).

Radiation

The association of radiation exposure with bladder cancer has been noted since atomic bomb survivors were found to have markedly increased rates of urothelial carcinoma. In one study, the attributable risk for survivors exposed to more than 0.005 Gy was estimated to be 16% and rose to 60% for those with more than 1 Gy of exposure. Urothelial cancer formation after radiation therapy does not appear age related; however, the estimated latency period is estimated to be 15 to 30 years. External beam radiation for cervical cancer is associated with a two- to fourfold higher incidence of secondary bladder cancer compared with the nonirradiated population (Boice et al., 1985; Kleinerman et al., 1995). Studies regarding the use of external beam radiation therapy (EBRT) and brachytherapy are conflicting and likely confounded by other risk factors for bladder cancer. However, they do suggest that EBRT for prostate may denote a 1.5-fold to twofold increased risk of bladder cancer (Chrouser et al., 2005; Nieder et al., 2008). Brachytherapy appears to be associated with a smaller risk, and several investigators have suggested that intensity-modulated radiation therapy denotes little to no increased risk of bladder tumor formation (Hall and Wuu, 2003).

Chemotherapy

Chemotherapy destroys malignant cells by inducing DNA damage and cell death; however, in organs with rapid cell turnover, chemotherapy can induce dysregulation for normal cells. The only chemotherapy that has been shown to cause bladder cancer is cyclophosphamide. Phosphoramide mustard is the primary mutagenic metabolite that causes cyclophosphamide-associated bladder cancer. The risk of bladder cancer is 4.5-fold higher among patients who underwent cyclophosphamide treatment and appears to be dose dependent and most pronounced among those who receive more than 20 g. For patients who receive more than 50 g of cyclophosphamide, the excess risk increases to approximately 7 excess cases per 100 patients treated (Travis et al., 1995). In addition, the risk appears to increase after 5 years of cyclophosphamide treatment and peaks in years 10 to 14, with standardized incidence ratios of up to 15% (Faurschou et al., 2015).

Environmental Pollution

Exposure to arsenic in drinking water has been associated with the development of urothelial bladder cancer. Arsenic is a toxic metalloid that enters drinking water from weathering rock. West Bengal, Bangladesh, and Taiwan are the most affected regions worldwide with concentrations in excess of 4700 μg/L, a 470-fold increase over the recommended amount of 10 μg/L. Studies in these regions and parts of Chile, where arsenic exposure is particularly high, have confirmed a significantly higher rate of bladder cancer in these regions (Burger et al., 2013). The mechanism of arsenic-mediated carcinogenesis is thought to be multifactorial, including oxidative stress, epigenetic effects, and alterations in DNA repair.

Diet

Fluids

Similar to other cancers, dietary factors have been an area of much study with regard to bladder cancer risk. Fluid intake is one area of controversy, as initial retrospective studies demonstrated decreased bladder cancer risk with increased water consumption (Burger et al., 2013). However, these findings were not demonstrated in the European Prospective Investigation into Cancer and Nutrition (EPIC), which showed no link between total fluid intake and bladder cancer risk among 250,000 patients with a mean of 9 years follow-up (Ros et al., 2011). Similarly, caffeine consumption through ingestion of coffee and tea have not been shown to be associated with bladder cancer risk (Al-Zalabani et al., 2016). The studies that initially demonstrated a modest link between coffee consumption and bladder cancer were confounded by smoking (Villanueva et al., 2009). Alcohol is a known risk factor for several cancers primarily involving the gastrointestinal tract and the hepatobiliary system. However, there is currently no evidence to support a link between alcohol consumption and bladder cancer risk, regardless of the amount of alcohol consumed (Bagnardi et al., 2015).

Foods

In addition to fluid intake, many carcinogens are ingested via food and excreted in the urine resulting in direct exposure to the urothelium and potential for increased bladder cancer risk. **However, no conclusive data support consumption of a specific food or food group to mitigate bladder cancer risk.** In other malignancies dietary intake of meat has been associated with increased risk. However, among more than 500,000 persons in the EPIC study, red meat consumption was not associated with bladder cancer risk. Dietary intake of fruits and vegetables has been investigated because they are an abundant source of phytochemicals with purported anti-carcinogenic effects. In the EPIC study, a higher consumption of fruits and vegetables was associated with lower risk of bladder cancer among never and former smokers but not in current smokers. Furthermore, in meta-analyses adjusting for smoking status, no associations between bladder cancer and total fruits and vegetables, total vegetable, or total fruit intake were identified (Ros et al., 2011; Vieira et al., 2015).

Dietary Supplements

Similar to fluid and food intake, no supplemental vitamin and minerals have been shown to have carcinogenic or protective effects for bladder cancer. In a prospective series of 80,000 persons in the VITamins study, no supplements were identified to be related to bladder cancer risk. Similarly, in the Selenium and Vitamin E Cancer Prevention Trial (SELECT), no association between selenium and vitamin E and bladder cancer was identified.

Key Points

- Bladder cancer is related to age and exposure to environmental carcinogens.
- Smoking accounts for 30% to 40% of all urothelial carcinoma.
- Although bladder cancer is more than 3 times as prevalent in men, women are more likely to be seen initially with more advanced tumors and less

favorable prognosis.

- Bladder cancer is the most expensive cancer to treat per patient over a patient's lifetime.
- No dietary interventions have been successful at reducing risk from bladder cancer.

Detection of Urothelial Carcinoma

Unlike many cancers, bladder cancer is rarely incidentally discovered at the time of autopsy. Painless gross hematuria is present in 85% of patients with newly diagnosed bladder cancer, and microscopic hematuria is present in nearly all patients (Alishahi et al., 2002; Edwards et al., 2006). Hematuria is typically intermittent and can be related to Valsalva maneuvers. Importantly, any episode of gross hematuria must be evaluated even if subsequent urinalysis is negative. Use of anti-platelet therapy and anticoagulation should similarly not preclude a full hematuria evaluation (Davis et al., 2012). Irritative voiding symptoms (e.g., frequency, urgency) also may be signs of bladder cancer, particularly carcinoma in situ (CIS).

Approximately 50% of patients with gross hematuria have an identifiable cause, and the risk of malignancy in these patients is 20.4%. By comparison, the risk of malignancy among patients with microscopic hematuria is 2.6% to 5.2% (Davis et al., 2012; Khadra et al., 2000). The risk of malignancy among patients with recurrent gross or microscopic hematuria who had a complete negative hematuria workup is nearly 0 within the first 6 years. As a result, it is reasonable to delay a repeat hematuria evaluation in patients with persistent hematuria 3 to 5 years after their first negative evaluation (Davis et al., 2012; Khadra et al., 2000).

Hematuria is defined as the presence of red blood cells (RBCs) in the urine. The urine dipstick is a common test that screens for hematuria by using reagents that detect peroxidase activity of heme in RBCs. However, although the sensitivity is for urine dipsticks in detecting hematuria is 91% to 100%, the reported specificity of dipstick tests is 65%, which can lead to unnecessary hematuria evaluations (Liu et al., 2016). In contrast, microscopic urinalysis directly examines the urine sediment for the presence of RBCs. For this reason, urine dipstick is discouraged as the sole screening test for microhematuria and should be confirmed with microscopic urinalysis (American Urological Association, 2015).

A full hematuria evaluation for bladder cancer includes a focused history and physical, cystoscopy, upper tract imaging, and a urine culture. For patients with gross hematuria upper tract imaging should include a multi-phase computed tomography (CT) scan with delayed phase images for patients who can tolerate it. Although 2012 AUA guidelines suggest a CT urogram (CTU) for the evaluation of asymptomatic microhematuria (AMH) as well, recent studies suggest CTU can be safely replaced with a renal and bladder ultrasound in patients with AMH because upper tract malignancy is exceedingly rare in these patients (Tan et al., 2018). For patients with gross hematuria it is reasonable to obtain a urine cytology and/or urine markers. However, according to the AUA guidelines, providers should avoid obtaining urine cytology or urine markers as part of the routine evaluation of the asymptomatic patient with microhematuria (Davis et al., 2012). A focused history should inquire into patient risk factors as outlined earlier as well as family history. Although physical exam will rarely uncover a bladder tumor, a bimanual exam should be performed at the time of transurethral resection of the bladder tumor if the tumor appears invasive. A prostate-specific antigen (PSA) blood test may be considered after a discussion between the patient and provider because 10% of patients with recurrent gross hematuria will have prostate cancer.

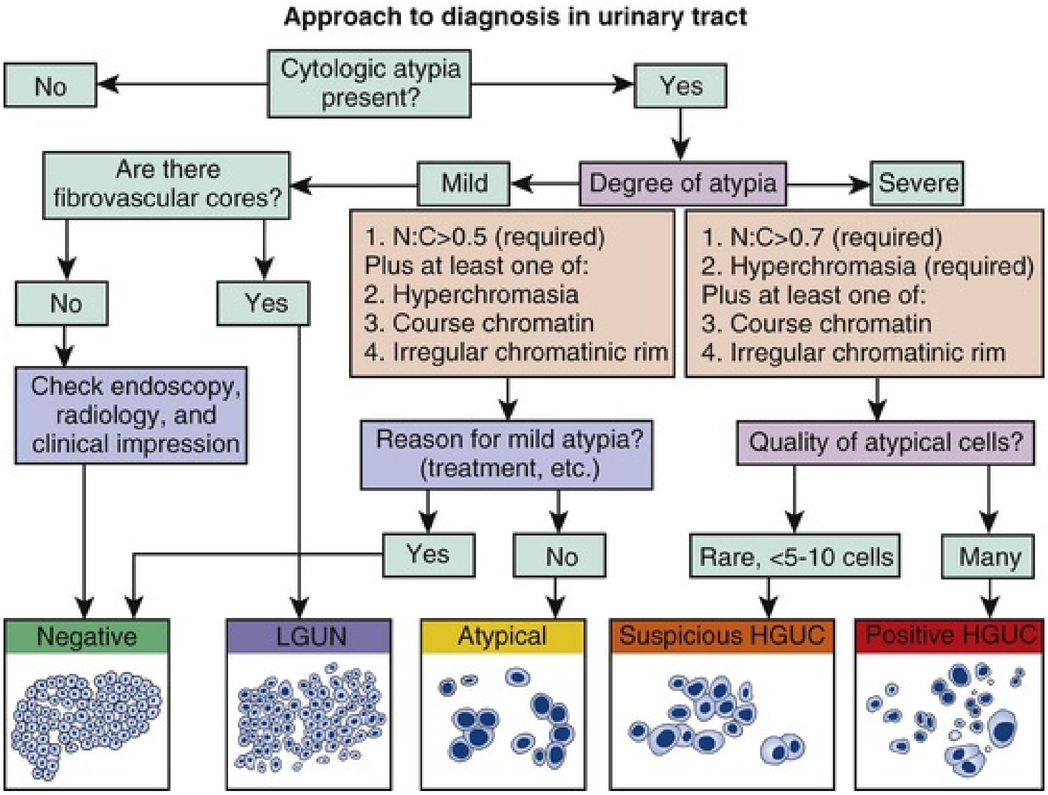
Cystoscopy

The gold-standard test for the diagnosis of bladder cancer is cystoscopy and biopsy. All adult patients with gross hematuria and all patients 35 years and older with microscopic hematuria should undergo cystoscopic evaluation for malignancy. Flexible office cystoscopy is as reliable for the diagnosis of bladder cancer as rigid endoscopy (Grossfeld et al., 2001). Currently white light cystoscopy (WLC) remains the standard of care for the diagnosis of a bladder tumor and enables the urologist to map and resect all visible tumors. Although WLC has excellent sensitivity and specificity for the diagnosis of large papillary tumors, it is less reliable for diagnosing small papillary tumors and CIS. Porphyrin-induced fluorescence cystoscopy uses photoactive porphyrins, such as hexaminolevulinate (HAL), that accumulate preferentially in neoplastic tissue and emit red fluorescence under blue-wavelength light with a wavelength of 360 to 450 nm. Although HAL and 5-aminolevulinic acid (5-ALA) have been assessed in clinical studies, only HAL is FDA approved, with indications for bladder cancer surveillance for rigid and flexible cystoscopy (Video 135.1▶). In a meta-analysis assessing the utility of HAL-blue light cystoscopy (BLC), BLC detected 14.7% more Ta tumors and 40.8% more CIS lesions compared with WLC (Burger et al., 2013). In 26.7% of patients, CIS was detected only by BLC, and detection was significantly improved for primary bladder cancer diagnosis and recurrent cancer diagnosis. In the outpatient setting, flexible BLC identified a tumor recurrence not seen under WLC in 20.6% of patients (Daneshmand et al., 2018).

Narrow band imaging (NBI) is an endoscopic optical image enhancement technique that enhances contrast between mucosal surfaces and microvascular surfaces without the use of dyes. The depth of light penetration into the bladder wall increases with increasing wavelength. NBI illuminates the mucosal surface with light of a narrow bandwidth in the blue (415 nm) and green (540 nm) light spectrum, which are strongly absorbed by hemoglobin. Consequently the vascular structures appear dark brown or green against a pink or white mucosal background. Studies evaluating NBI have been performed primarily in single-institution settings or have been underpowered; nevertheless, NBI appears to improve the detection of CIS compared with WLC alone. However, in the most robust study performed thus far, a multicenter randomized trial comparing NBI-assisted transurethral resection of bladder tumor (TURBT) to conventional white light TURBT, NBI and WLC achieved similar overall 12-month recurrence rates (27% in WLC and 25.4% in NBI), but NBI-assisted TURBT significantly reduced disease recurrence in low-risk patients (27% in WLC vs. 5.6% in NBI) (Naito et al., 2016).

Urine Cytology

Since 1945, when George Papanicolaou first hypothesized that exfoliated cells in urine could reliably detect urinary tract malignancies, urine cytology has been a standard diagnostic test to aid in the diagnosis of bladder cancer. The contemporary sensitivity and specificity for urine cytology in detecting bladder cancer is 31% to 62% and 94% to 100%, respectively (Planz et al., 2005; Raitanen et al., 2002; van Rhijn et al., 2005). Furthermore, significant variation in cytologic reporting exists between institutions, further complicating the interpretation of this subjective diagnostic modality (Karakiewicz et al., 2006; Raitanen et al., 2002). In 2013 Paris Reporting System for urinary cytology was first introduced at the International Congress of Cytology to standardize cytologic interpretation of urine samples (Fig. 135.5; Rosenthal et al., 2017). This reporting schema emphasizes specific diagnostic categories and cytomorphologic criteria for the reliable diagnosis of high-grade urothelial carcinoma. Preliminary reports suggest that the Paris classification schema may decrease the rate of inconclusive “atypia” calls and improve risk stratification for patients with high-grade urothelial carcinoma (Cowan et al., 2017; Wang et al., 2018). Because urine cytology is highly specific, a cytology suspicious or positive for high-grade urothelial carcinoma should be investigated. In a patient with a negative cystoscopy and persistent positive high-grade urine cytology, it is therefore reasonable to perform random biopsies of the bladder and prostatic urethra, as well as ureteral washings for cytology with or without direct ureteroscopic inspection of the upper tracts.



Approach to diagnosis in urinary tract
Cytologic atypia present?
No

(Modified from Barkan GA, Wojcik EM, Nayar R, et al.: The Paris System for reporting urinary cytology: the quest to develop a standardized terminology. *Acta Cytol* 60:185–197, 2016.)

Urine-based biomarkers have been developed as an adjunct to standard diagnostic modalities for bladder cancer diagnosis and monitoring. Noninvasive testing with improved sensitivity over urine cytology has been proposed as a desirable alternative to cystoscopy, which is costly and uncomfortable. Several urine-based biomarkers have been developed with improved sensitivity compared with urine cytology, although most have yet to reach its specificity. We will discuss the most widely available and reported urinary biomarkers that have relevance in current and future clinical practice (Table 135.2).

BTA, Bladder tumor antigen; *CI,* confidence interval; *FISH,* fluorescence in situ hybridization; *LR,* likelihood ratio; *NMP22,* nuclear matrix protein 22.

Data from Chou R, Gore JL, Buckley D, et al.: Urinary biomarkers for diagnosis of bladder cancer: a systematic review and meta-analysis. *Ann Int Med* 2015 (online journal): http://annals.org/aim/fullarticle/2466370/urinary-biomarkers-diagnosis-bladder-cancer-systematic-review-meta-analysis.

Nuclear matrix protein 22 (NMP22) is part of a family of proteins that provides structure to cell nucleus and is 20 times more prevalent in malignant urothelial cells compared with normal cells. There are currently 2 NMP22 tests FDA approved for use in BC surveillance: the original NMP22 laboratory-based quantitative test and a point-of-care qualitative test. In a meta-analysis of 19 studies, sensitivity of quantitative NMP22 was 0.69 (95% CI 0.62–0.75), and specificity was 0.77 (95% CI 0.70–0.83). Diagnostic accuracy appears to be similar for initial diagnosis as well as surveillance. Sensitivity of the qualitative point of care NMP22 tests was 0.58 (95% CI 0.39–0.75) and specificity was 0.88 (95% CI 0.78 to 0.94), although these ranges are limited by relatively few studies.

Fluorescence in Situ Hybridization

Fluorescence in situ hybridization (FISH) has been designed for bladder cancer detection since 2000 and identified fluorescently labeled DNA probes that bind to intranuclear chromosomes (Sokolova et al., 2000). The current commercially available FISH assay (UroVysion) detects aneuploidy of chromosomes 3,7, and 17, and homozygous loss of the 9p21 locus in exfoliated urothelial cells. A positive test is defined as 5 or more urinary cells with gains of two or more chromosomes, 10 or more cells with gain of a single chromosome, or homozygous deletion of 9p21 in more than 20% of exfoliated cells. Overall sensitivity of FISH is 0.63 (95% CI 0.50–0.75) and specificity 0.87 (95% CI 0.79–0.93) (Chou et al., 2015). As a reflex test in the setting of an atypical cytology, a negative FISH correlates with benign cytologic changes. Among patients with an atypical cytology and a negative cystoscopy, 3-year recurrence-free survival increases from 34% to 67% in the setting of a positive FISH (Kim et al., 2014; Yoder et al., 2007). FISH has relative low sensitivity in detecting low-grade bladder tumors, and there continues to be a lack of consensus regarding criteria used to evaluate abnormal cells.

Bladder Tumor Antigen

The bladder tumor antigen (BTA) assay detects two basement membrane antigens, human complement factor H-related protein and complement factor H using monoclonal antibodies. Two forms of the BTA test are available and FDA approved for the diagnosis and follow-up of bladder cancer. The BTA stat test is a qualitative dipstick-based point-of-care test. Sensitivity of qualitative BTA was 0.64 (95% CI 0.58–0.69) across 22 studies, and specificity was 0.77 (95% CI 0.73–0.81). In addition, a quantitative, ELISA-based BTA assay (BTA TRAK) has also been developed, with reported sensitivity of 0.65 (95% CI 0.54–0.75) and specificity of 0.74 (95% CI 0.64 to 0.82). The high false positivity of both BTA assays could be related to the presence of cross-reactivity with red blood cells because complement factor H is present in high concentrations in serum and thus is associated with high false positives in hematuria (Longo et al., 2018).

Immunocyt

Immunocyt is a cell-based adjunct to urine cytology, developed in the late 1990s. Fluorescent-labeled antibodies are directed against three antigens that are commonly expressed by exfoliated urothelial cells: a glycosylated from of carcinoembryonic antigen (CEA) and two mucins. Across all studies, the sensitivity of ImmunoCyt was 0.78 (95% CI 0.68–0.85), and specificity was 0.78 (95% CI 0.72–0.82) (Chou et al., 2015). In one study, ImmunoCyt in combination with urine cytology improved sensitivity from 50% to 90%; however, specificity was lower (80% to 72%) when compared with cytology alone (Toma et al., 2004). Like urine cytology, the test is operator dependent, with high interobserver variability and poor agreement (Pode et al., 1999); one study has suggested that the variability in test performance can be overcome with adequate training (Messing et al., 2005).

CxBladder

CxBladder is a cell-based urine assay that comprises five mRNA fragments (HOXA13, CDC2, MDK, CXCR2, and IGFBP5) (Holyoake et al., 2008; O'Sullivan et al., 2012). With a limited number of studies performed thus far, test sensitivity is approximately 85% and specificity 85% (Kavalieris et al., 2015; O'Sullivan et al., 2012). Although still in need of validation in independent, multi-institutional datasets, initial comparative studies have suggested the CxBladder may have improved sensitivity and specificity over urine cytology and other protein-based assays (Breen et al., 2015; Lough et al., 2018).

The currently available urinary biomarkers to detect bladder cancer miss many patients with bladder cancer and yield false positives in others. Head-to-head comparisons of urinary biomarkers have been too limited thus far to reach firm conclusions about comparative effectiveness. It is thus our opinion and current practice that in the setting of microhematuria, the addition of any current urine biomarkers does not preclude a cystoscopy and thus does not change management. Similarly, in the case of gross hematuria, a negative test result is associated with an approximately 10% probability of having bladder cancer (Longo et al., 2018). As a result, a negative test would also not preclude a cystoscopy. Furthermore, the field is rapidly evolving with the discovery of novel genomics and bladder cancer subtypes. Multiplex gene assays have been developed by multiple teams and are in need of further validation. Because none of the currently available biomarkers have reached the necessary threshold for the diagnosis of bladder cancer, they are currently used in combination with cystoscopy as a surveillance strategy for patients with a known history of non–muscle-invasive bladder cancer.

Key Points

- Painless gross hematuria is the key presenting symptom of bladder cancer, occurring in 85% of newly diagnosed patients.
- A full hematuria evaluation for bladder cancer includes a focused history and physical, cystoscopy, upper tract imaging, and a urine culture.
- The gold-standard test for the diagnosis of bladder cancer is cystoscopy and biopsy. Increasingly, HAL BLC and narrow band imaging are being used as adjuncts to cystoscopy in identifying occult malignancy.

- There are various urine markers that can be used to evaluate secreted proteins or shed cells in the hope of noninvasively detecting bladder cancer. None of these markers has a high enough sensitivity or specificity to replace office cystoscopy.

Pathology

There are numerous benign tumors of the bladder, each with its own clinical presentation and disease burden.

Epithelial Metaplasia

Epithelial metaplasia is defined by focal area of transformed urothelium, with otherwise normal nuclear and cellular morphology. Typically, epithelial metaplasia is located on the trigone and may be composed of either squamous metaplasia or glandular metaplasia. Glandular metaplasia in particular consists of clumps of raised, red inflammatory areas that can be confused for cancer. Squamous metaplasia is very common, affecting up to 40% of women and 5% of men, and can be attributed to a history of urinary tract infection, trauma, and prior surgery (Ozbey et al., 1999). A biopsy to diagnose glandular or squamous metaplasia is unnecessary and no treatment is required or efficacious.

Papilloma and Inverted Papilloma

An inverted papilloma (Fig. 135.6) is a benign proliferative lesion that is associated with chronic inflammation or bladder outlet obstruction and can be located throughout the bladder but most commonly on the trigone, accounting for less than 1% of all bladder tumors. Painless gross hematuria is the most common representing symptom, with microscopic hematuria and irritative voiding symptoms also common. Inverted papillomas grow in an endophytic pattern along the lamina propria to form nests and anastomosing trabeculae. When diagnosed according to strictly defined criteria (e.g., lack of cytologic atypia), inverted papillomas behave in a benign fashion with a 1% chance of recurrence.

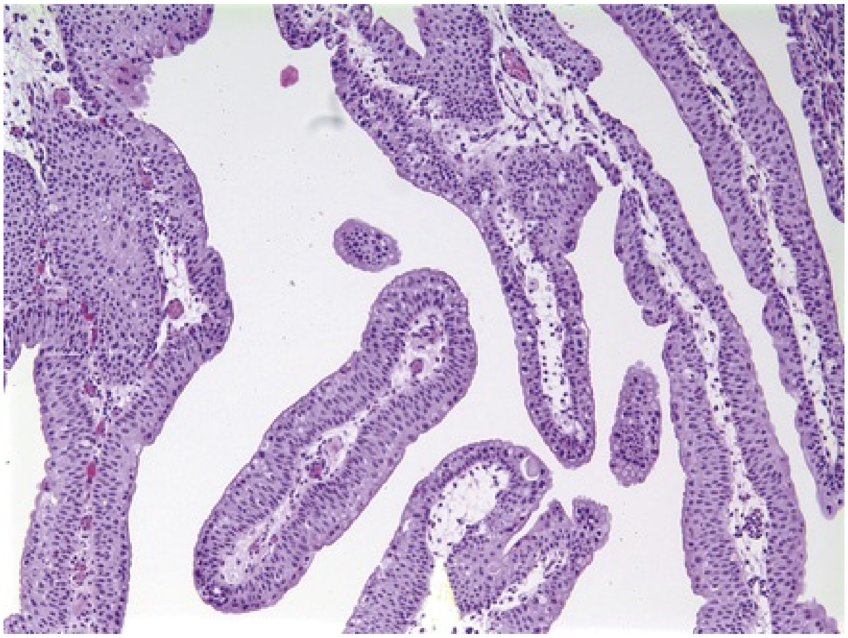

FIG. 135.6 Inverted papilloma.

Urothelial papilloma (Fig. 135.7) is characterized by a benign proliferative growth of delicate stalks lined by normal-appearing urothelium. Papillomas were historically characterized as low-grade Ta malignant bladder tumors but are now thought to be benign with no risk of local or systemic invasion. Although papillomas have fibroblast growth factor receptor-3 (FGFR3) mutations, which are commonly found in bladder cancer, they lack markers of aggressive behavior, including TP53 and RB mutations (Montironi and Lopez-Beltran, 2005).

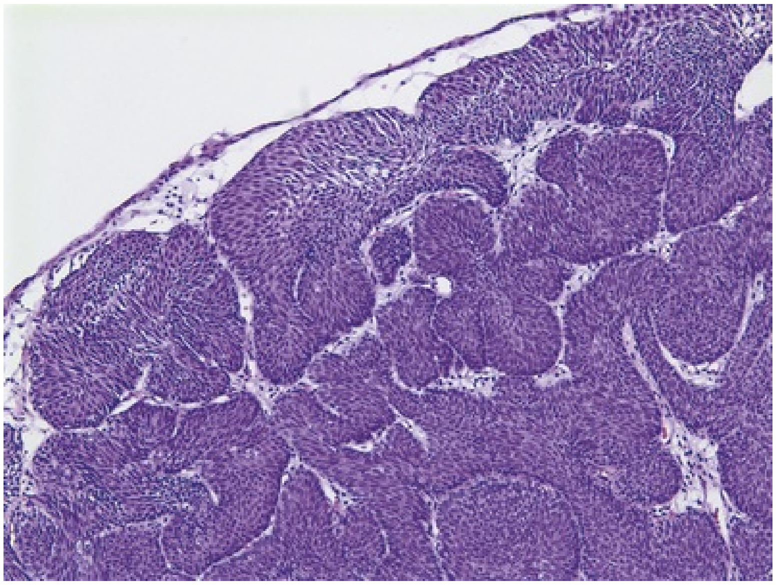

FIG. 135.7 Papilloma.

Nephrogenic Adenoma

Nephrogenic adenoma is a rare tumor caused by chronic irritation of the urothelium and can arise from trauma, prior surgery, renal transplantation, intravesical chemotherapy, stones, catheters, and infection. Nephrogenic adenoma is composed of glandular appearing tubules similar to renal tubules that involve mucosa and sub mucosa of the bladder. Cystoscopically, nephrogenic adenoma may appear like a papillary neoplasm and may be hard to distinguish from more aggressive bladder neoplasms. Lesions may cause dysuria hematuria, prompting cystoscopic investigation. Recurrence does occur but is uncommon and can be safely managed with repeat resection (Yi et al., 2018).

Leukoplakia

Leukoplakia of the bladder has similar features to squamous metaplasia with the additional characteristic of white, flaky plaques floating in the bladder. If not diagnosed incidentally, presenting symptoms are typically frequent, recurrent infections with urinary urgency and frequency. Histologic analyses demonstrate that the bladder mucosa is chronically inflamed, displaying diffuse squamous metaplasia of keratinizing type leukoplakia. Although on other squamous epithelial surfaces leukoplakia is premalignant, there exists some controversy as to whether bladder leukoplakia predisposes patients to malignancy. Historic reports described leukoplakia as premalignant, with 37% risk of carcinoma (Benson et al., 1984). However, more recently a connection between leukoplakia as an independent risk factor for bladder cancer has been disproven. Staack et al. (2006) performed cytogenic studies of bladder leukoplakia in 77 cases using DNA analysis for tumor suppressor gene TP52 and found no evidence to suggest that this condition was premalignant; therefore cystoscopy, biopsy, and further treatment were unnecessary.

Cystitis Cystica and Glandularis

Cystitis cystica and/or glandularis is a common finding in normal bladders, typically associated with inflammation or chronic obstruction. These benign lesions represent cystic nests that are lines by columnar or cuboidal cells and are generally associated with proliferation of Von Brunn nests (Fig. 135.8) (Semins and Schoenberg, 2007). Although cystitis glandularis (Fig. 135.9) can transform into adenocarcinoma, the risk is low; however, regular endoscopic evaluation of these entities is recommended. Treatment is transurethral resection and relief of the obstruction or inflammatory condition.

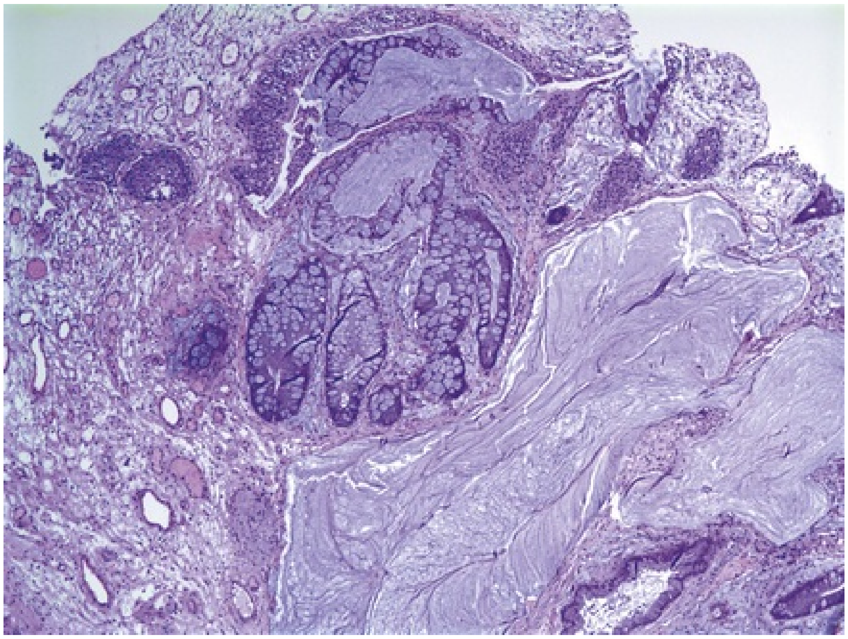

FIG. 135.8 Von Brunn nest with cystitis cystica.

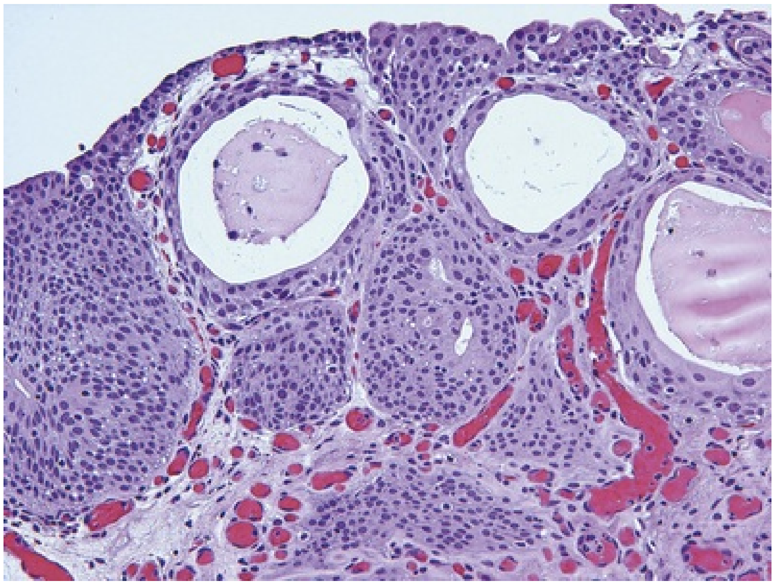

FIG. 135.9 Cystitis glandularis.

Precursor Malignant Lesions

Normal urothelium comprises multilayered mucosa, 4 to 7 cells thick, which features the transition between nonkeratinizing squamous and pseudostratified columnar epithelium. Cells mature from the basal basement membrane cells, which are small and cuboidal, to intermediate cells to superficial umbrella cells in an orderly fashion. The surface has large umbrella cells that may have nuclear atypia and form asymmetrical units. These umbrella cells form a urine bladder barrier preventing toxins from transforming urothelial cells. Precursor lesions are a continuum from hyperplasia to atypia to dysplasia and finally cancer. The 2004 World Health Organization classification system for urothelial neoplasia classifies pre-malignant lesions as urothelial hyperplasia (flat and papillary), reactive atypia, urothelial atypia of unknown significance (AUS), urothelial dysplasia, and low-grade intraurothelial neoplasia (Hodges et al., 2010).

Urothelial hyperplasia may be flat or papillary (Fig. 135.10) and is characterized by thickening of the mucosa to 10 or more cell layers. Although the nuclei may be slightly enlarged, no cytologic atypia is present and mitoses are absent. Although in isolation urothelial hyperplasia is not thought to have malignant potential, hyperplasia is frequently seen in conjunction with pre-malignant and malignant lesions. Hyperplastic flat lesions may be precursors to low-grade papillary tumors, evidenced by mutation in FGFR3, and loss of heterozygosity at 3q22-q24, 5q22-q31, 10q26, 13q14, and 17p13 in benign hyperplastic lesions from bladders with urothelial carcinoma (Majewski et al., 2008; van Oers et al., 2006). On cystoscopy, papillary urothelial hyperplasia can be indistinguishable from low-grade papillary lesions and is often present adjacent to low-grade papillary tumors.

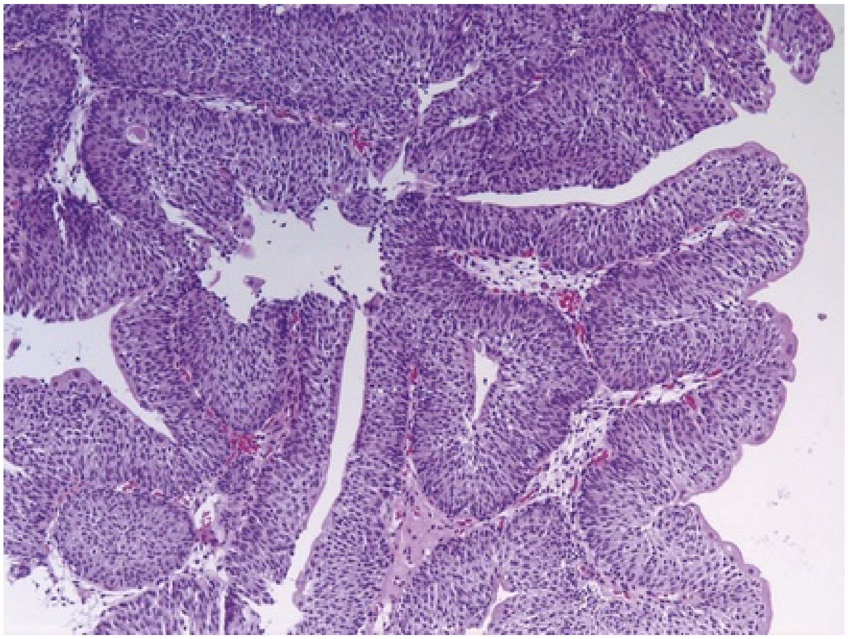

FIG. 135.10 Papillary urothelial hyperplasia.

Reactive atypia is characterized by nuclear abnormalities occurring in the background of an inflamed urothelium (Hodges et al., 2010). Typically patients have a history of chronic inflammation, regeneration, or reaction from noxious stimuli and have irritative voiding symptoms. Endoscopically, reactive atypia is edematous and inflamed appearing. Microscopically, although nuclei may be prominent and enlarged, the mucosa proceeds in an orderly fashion from basal to intermediate to superficial cell types, and nuclear polarity is maintained. Similar to hyperplasia, reactive atypia does not appear to independently evolve into carcinoma; however, atypia often coexists with dysplasia and carcinoma in situ and thus mandates rigorous investigation.

Atypia of unknown significance (AUS) is used when it is unclear whether observed urothelial changes are premalignant or reactive. Microscopically, AUS is characterized by inflammation of the lamina propria and nuclear atypia disproportionate to the degree of atypia. CK20 and CK44 immunohistochemical staining, which are positively expressed in AUS, can aid in distinguishing AUS from dysplasia (Kunju et al., 2005). AUS independently does not appear to lead to urothelial carcinoma and is a diagnosis of limited clinical utility.

Urothelial dysplasia is characterized by a normal urothelial thickness and an altered cytologic appearance of urothelial cells. Normal cytoplasmic clearing is lost particularly in basal and intermediate cells, with loss of nuclear polarity, nuclear enlargement, hyperchromosia, and nuclear membrane irregularity. The lamina propria is typically normal, and comparison with normal urothelium can help differentiate reactive atypia from dysplasia. Ck20 and P53 staining typically highlight the dysplastic cells. Umbrella cells are typically present with dysplasia but not with CIS. Dysplasia, although difficult to distinguish from CIS in some cases, is a good indication of urothelial instability and a marker of recurrence or progression in those with a history of urothelial cancer. Approximately 14% to 19% of patients with urothelial dysplasia will progress to urothelial cancer; however, in the setting of a prior history of bladder cancer, urothelial dysplasia will lead to CIS in 60% of cases (Baithun et al., 1988; Cheng et al., 1999, 2000).

Malignant Lesions

Urothelial carcinoma is the most common malignancy of the urinary tract and is the second most common cause of death among all genitourinary tumors. Non–muscle-invasive bladder cancer, comprising low- and high-grade noninvasive papillary neoplasms, CIS, and urothelial carcinoma with invasion into the lamina propria (T1), make up approximately 70% of all bladder urothelial carcinoma.

CIS (Fig. 135.11) is characterized by noninvasive, flat high-grade tumors. There is severe nuclear atypia, loss of cellular polarity, and a non-cohesive cellular structure. The cells are large, pleomorphic, chromatin clumping, and often with abnormal mitotic figures. A characteristic that separates dysplasia from CIS is the loss of umbrella cells. The genetic abnormalities of CIS are more similar to high-grade, invasive tumors of the urinary tract, furthering the concept that CIS is a precursor to high-grade invasive carcinoma. These include alterations to RB, TP53, and PTEN (Sanchez-Carbayo et al., 2002). Interestingly, no FGFR3 mutations have been reported in CIS, suggesting a very different tumor lineage from low-grade papillary tumors, which have frequent FGFR3 mutations (Zieger et al., 2009). Clinically, CIS in association with invasive tumors carries a worse prognosis, with a 45% to 65% 5-year mortality rate (Montironi et al., 2009).

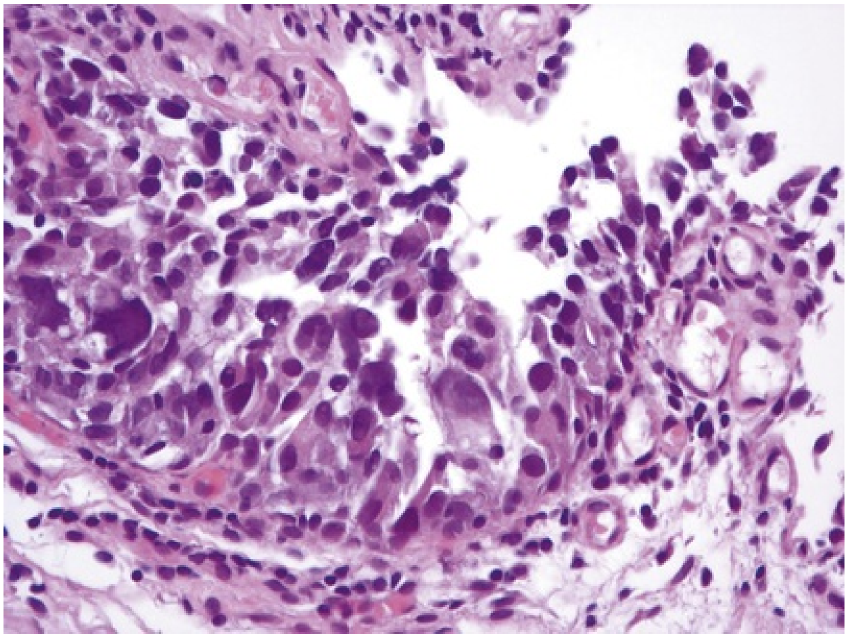

FIG. 135.11 Carcinoma in situ.

Papillary urothelial neoplasm of low malignant potential (PUNLMP) (Fig. 135.12) constitutes a diagnosis with particularly good prognosis, and there is controversy as to whether it should carry the label of cancer (Montironi and Lopez-Beltran, 2005; Sauter, 2004). PUNLMP is a papillary growth with minimal cytologic atypia that is more than seven cells thick, generally solitary, and typically located on the trigone. Cell polarity is maintained, and nuclei are mildly enlarged. Five-year recurrence rates after PUNLMP are estimated to be 20.1%, and these recurrences are nearly always PUNLMP or low-grade papillary lesions. Progression to MIBC among patients with PUNLMP is less than 1%, and it is unclear if these rare high-grade recurrences represent true stage progression or the presence of a new, separate bladder cancer (Maxwell et al., 2015). TERT promoter mutations and FGFR3 mutations have been identified in more than 60% of PUNLMP cases, which creates a similar profile to low-grade papillary Ta lesions. The low rate of HRAS mutations (3%) compared with the 33% incidence in other noninvasive urothelial tumors, however, may speak to the relative indolent, non-aggressive course of PUNLMP lesions (Rodriguez Pena et al., 2017).

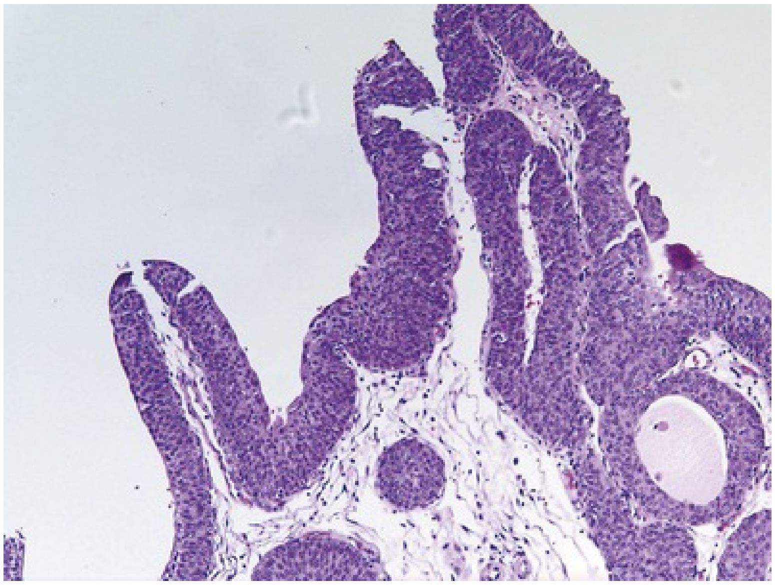

FIG. 135.12 Papillary urothelial neoplasm of low malignant potential.

Low-grade urothelial carcinoma is typically papillary (Fig. 135.13) with a fibrovascular stalk and frequent papillary branching with increased cellular size, some nuclear atypia, and occasional mitotic figures. These tumors almost universally display alterations of genes in chromosome 9 and frequent mutations in *FGFR3*, *PI3K* or, alternatively, *Ras* genes (Dinney et al., 2004; Lopez-Knowles et al., 2006; van Rhijn et al 2010). Low-grade Ta tumors frequently recur 48% to 71% of the time; however, stage or grade progression is relatively infrequent, occurring 2% to 12% of the time, depending on the series (Montironi and Lopez-Beltran, 2005).

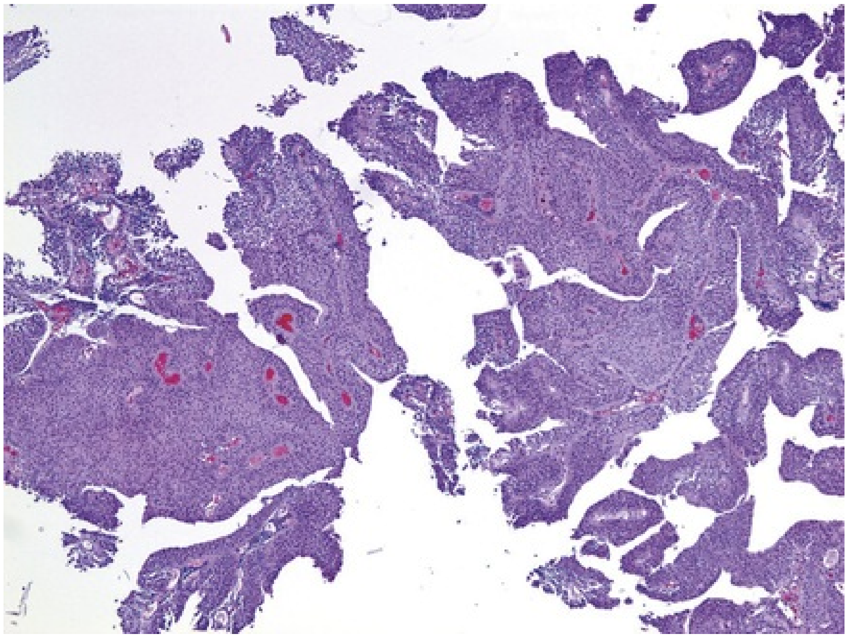

FIG. 135.13 Low-grade papillary urothelial neoplasm.

High-grade papillary urothelial cancer (Fig. 135.14) is composed of fused papillary stalk with high-grade cancer in the urothelial layer. There is a disordered growth pattern, numerous mitotic figures present, and there are pleomorphic cells with exaggerated nuclei. If left untreated, more than 80% of high-grade papillary tumors invade the underlying urothelial stroma. High-grade papillary tumors are considered biologically, and clinically, to be a precursor to invasive high-grade urothelial cancer.

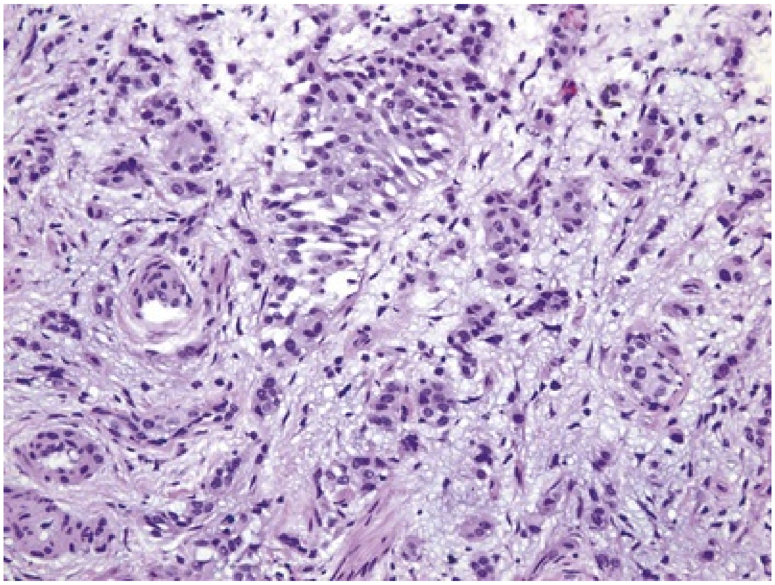

FIG. 135.14 High-grade urothelial cancer invading the lamina propria.

Staging

The American Joint Committee on Cancer (AJCC) in combination with the International Union Cancer Consortium meets regularly to determine tumor, nodes, and metastases (TNM) staging classification. The 2017 staging system is shown in Table 135.3 (Amin et al., 2017). Broadly speaking, non–muscle-invasive bladder cancer comprises stage 0 (noninvasive) and stage I (invasion into subepithelial connective tissue), muscle-invasive organ-confined bladder cancer is of stage II, muscle-invasive locally advanced bladder cancer is stage III, and metastatic disease is stage IV. Whereas prior AJCC editions viewed positive lymph nodes as stage IV regardless of the quantity or location, the 2017 AJCC staging update now views nodal disease in the absence of systemic metastases as stage III (Paner et al., 2018).

TABLE 135.3

American Joint Committee on Cancer/International Union Cancer Consortium 2017 Tumor, Nodes, and Metastases (TNM) Staging Classification

STAGE	STAGE GROUPING	STAGE DESCRIPTION
0a	**Ta**	The cancer is a noninvasive papillary carcinoma (Ta). It has grown toward the hollow center of the bladder but has not grown into the connective tissue or muscle of the bladder wall.
	N0	It has not spread to nearby lymph nodes (N0) or distant sites (M0).
	M0	
0is	**Tis**	The cancer is a flat, noninvasive carcinoma (Tis), also known as flat carcinoma in situ (CIS). The cancer is growing in the inner lining layer of the bladder only. It has not grown inward toward the hollow part of the bladder, nor has it invaded the connective tissue or muscle of the bladder wall.
	N0	It has not spread to nearby lymph nodes (N0) or distant sites (M0).
	M0	
I	**T1**	The cancer has grown into the layer of connective tissue under

		the lining layer of the bladder but has not reached the layer of muscle in the bladder wall (T1).
	N0	The cancer has not spread to nearby lymph nodes (N0) or to distant sites (M0).
	M0	
II	**T2a or T2b** **N0**	The cancer has grown into the inner (T2a) or outer (T2b) muscle layer of the bladder wall, but it has not passed completely through the muscle to reach the layer of fatty tissue that surrounds the bladder.
	M0	The cancer has not spread to nearby lymph nodes (N0) or to distant sites (M0).
IIIA	**T3a, T3b or T4a**	The cancer has grown through the muscle layer of the bladder and into the layer of fatty tissue that surrounds the bladder (T3a or T3b).
	N0	It may have spread into the prostate, uterus, or vagina, but it is not growing into the pelvic or abdominal wall (T4a).
	M0	The cancer has not spread to nearby lymph nodes (N0) or to distant sites (M0).
	OR	The cancer has:
	T1-4a	grown into the layer of connective tissue under the lining of the bladder wall (T1), OR
	N1	into the muscle layer of the bladder wall (T2), OR
	M0	into the layer of fatty tissue that surrounds the bladder, (T3a or T3b) OR
		it may have spread into the prostate, uterus, or vagina, but it is not growing into the pelvic or abdominal wall (T4a).
		AND the cancer has spread to a nearby lymph node in the true pelvis (N1).
		It has not spread to distant sites (M0).
IIIB		The cancer has:
	T1-T4a	grown into the layer of connective tissue under the lining of the bladder wall (T1), OR
	N2 or N3 **M0**	into the muscle layer of the bladder wall (T2), OR
		into the layer of fatty tissue that surrounds the bladder (T3a or T3b), OR
		it may have spread into the prostate, uterus, or vagina, but it is not growing into the pelvic or abdominal wall (T4a).
		AND the cancer has spread to 2 or more lymph nodes in the true pelvis (N2) or to lymph nodes along the common iliac arteries (N3).

		It has not spread to distant sites (M0).
IVA		The cancer has grown through the bladder wall into the pelvic or abdominal wall (T4b).
	T4b	The cancer has not spread to nearby lymph nodes (N0) or to distant sites (M0).
	N0	
	M0	
	OR	
	Any T	The cancer may or may not have grown through the wall of the bladder into nearby organs (Any T).
	Any N	It may or may not have spread to nearby lymph nodes (Any N).
	M1a	It has spread to a distant set of lymph nodes (M1a).
IVB	**Any T**	The cancer may or may not have grown through the wall of the bladder into nearby organs (Any T).
	Any N	It may or may not have spread to nearby lymph nodes (Any N).
	M1b	It has spread to 1 or more distant organs (such as the bones, liver or lungs) (M1b).

NMIBC is further subdivided into low-, intermediate-, and high-risk disease. Low-risk NMIBC comprises a primary (i.e., not recurrent), low-grade papillary (Ta), solitary tumors less than 3 cm. Intermediate-risk NMIBC is histologically confirmed by multiple and/or recurrent and/or large (>3 cm) low-grade Ta tumors. High-risk NMIBC involves tumors with any high-grade histologic features (i.e., CIS or T1) (Kamat et al., 2014). In addition, the 2017 AJCC recommends subcategorization of T1 urothelial carcinoma into T1a (superficial) and T1b (deep) lamina propria invasion (Fig. 135.15) to help stratify the heterogeneous group of T1 tumors, which are at a 50% risk of upstaging to T2 or higher and a 33% risk of being upstaged to non–organ confined (Badalato et al., 2011; Svatek et al., 2010). **These stratifications suggest that the deeper the tumor invades into the lamina propria, the worse the survival.**

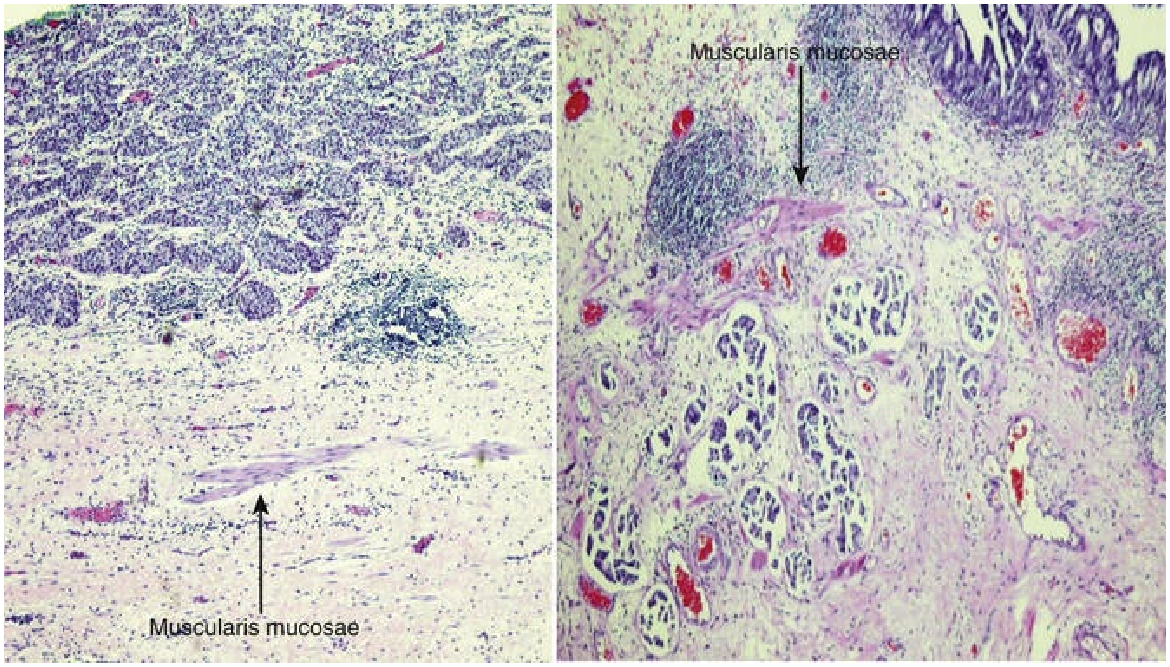

FIG. 135.15 High grade T1a *(left)* and Tlb *(right)* urothelial cancer.

Muscle-invasive disease is subdivided into T2a and T2b. T2a includes invasion into the inner half of the muscularis propria, although T2b is deeper into the outer half. It is controversial whether depth of muscle invasion makes significant impact on disease, and this is complicated by sampling variability of muscle on TURBT. For this reason, the AJCC staging guidelines view T2a and T2b as similar in the current staging schema. T3 disease constitutes invasion outside of the bladder proper into the periadipose tissue. T3a disease involves microscopic extension, whereas T3b is macroscopic extension. T4a disease is invasion of the prostatic stroma, uterus, or vagina, and T4b disease is invasion of the pelvic or abdominal wall.

Prostatic urethral cancer is associated with bladder cancer in 90% of cases, although among patients with primary bladder urothelial cancer, urethral involvement is relatively rare, occurring in 3% of patients. Most prostatic urethral urothelial carcinoma is CIS, and extension of the tumor into the prostatic urethra without stroma invasion does not carry an adverse prognosis for patients with known bladder cancer. These tumors can be difficult to treat with intravesical therapy, however, and as a result among patients undergoing frequent intravesical therapy, the rate of prostatic urethral CIS is elevated (Table 135.4; Mungan et al., 2005). Prostate stromal invasion, however, particularly if it is direct extension from the bladder through the muscle into the prostate, does carry a poor prognosis, with 5-year overall survival of less than 25% in historic series (Donat et al., 2001; Esrig et al., 1996). For this reason only patients with prostate stromal invasion are considered to be T4.

Molecular Biology

Major progress has been made in recent years toward improving our understanding of the molecular makeup of urothelial carcinoma. Several molecular alterations are common in bladder cancer, including FGFR3 alterations, PI3K pathway alterations, activation of mitogen-activated protein kinase (MAPK) signaling, defects in cell cycle regulation, and Hedgehog and WNT signaling (Knowles and Hurst, 2015).

Genes encoding proteins that control the cell cycle are frequently mutated in bladder cancer, particularly MIBC. Inactivation of *RB1*, and *CDKN2A* are very common, and *p53* inactivation occurs in as many as 76% of MIBCs (Cancer Genome Atlas Research Network, 2014). Similarly loss of the tumor suppressor gene *RB1* is common in MIBC and leads to amplification and overexpression of the oncogene *E2F3* (Knowles and Hurst, 2015). The genetic alterations that are the hallmark of NMIBC are alterations in the fibroblast growth factor receptor-3 *(FGFR3)* gene and deletions of chromosome regions 9p and 9q. Up to 80% of low-grade papillary (Ta) bladder tumors have activating point mutations in *FGFR3*, whereas approximately 10% to 20% of muscle-invasive bladder tumors have *FGFR3* mutations (Cappellen et al., 1999; Zieger et al., 2005). In normal bladder epithelium, FGFR3 is expressed in the IIIb isoform and binds to FGF1. In bladder cancer cell lines, a switch from the IIIb to the IIIc FGFR3 isoform may induce oncogenesis via paracrine and autocrine signaling (Tomlinson et al., 2005; Zhang et al., 2006). In addition, FGFR3 fusion proteins, which are present in many bladder tumors, comprise highly activated oncoproteins of FGFR3 fused to TACC3 or BAI1 (Williams et al., 2013).

The MAPK signaling pathway comprises another set of key genetic alterations in bladder cancer pathogenesis. *Ras* (HRAS or KRAS) pathway alterations are mutually exclusive from *FGFR3* mutations because they are in the same RAS-MEK-ERK pathway. *Ras* genes are from a family of transforming oncogenes that were originally identified in T24 bladder cancer cell lines (McBride et al., 1982). However, unlike *FGFR3*, *RAS* mutations occur with equal incidence in NMIBC and MIBC.

Point mutations in PIK3CA are found in 25% of NMIBC and less commonly in MIBC. FGFR3 and PIK3CA work together in a similar pathway, and thus both mutations are often seen in the same tumors. PI3K pathway alterations are critical in the PTEN pathway as PTEN negatively regulates PI3K. Downregulation of PTEN in MIBC is associated with TP53 alterations and poor prognosis (Platt et al., 2009; Puzio-Kuter et al., 2009). In a pre-clinical transgenic model of bladder cancer, dual deletion of the genes encoding p53 and PTEN leads to the development of metastatic bladder cancer (Knowles and Hurst 2015). It appears that the protein phosphatase activity of PTEN, and not its lipid activity, drives bladder cancer invasion and metastasis (Gildea et al 2004). Additional studies demonstrate that the WNT/b-catenin pathway often coordinates with PI3K/PTEN to promote bladder cancer development and growth. Three dimensional organoid cultures have revealed the importance of the WNT/b-catenin pathway in bladder cancer cell proliferation (Yoshida et al 2018). These studies confirmed earlier experiments showing that expression of activated b-catenin with PTEN deletion promoted bladder cancer development (Ahmad et al 2011).

A new framework is emerging for understanding the heterogeneity of bladder cancer and how that molecular diversity plays a role in treatment response. Historically, bladder tumors were thought to arise from two distinct pathways. In the first pathway, tumors arise from urothelial proliferation and differentiate into low-grade noninvasive papillary tumors. These tumors are enriched in *FGFR3* mutations and have a relatively low total mutational burden. In the second pathway, tumors start as dysplastic cells and transform into CIS and into high-grade invasive tumors.

However, recent genome-wide expression and sequencing studies have identified genes and pathways that are clear drivers in urothelial cancer development. A more complex picture with molecular subclasses that are agnostic to conventional tumor stage and grade has emerged.

In 2014, the comprehensive molecular characterization of MIBC was performed by the Cancer Genome Atlas (TCGA) (Network TCGAR 2014). In that analysis of mRNA, microRNA, and protein expression from 129 muscle invasive tumors, four distinct clusters were identified resembling intrinsic subtypes of breast cancer. Subdividing urothelial bladder cancer into intrinsic subtypes based on breast cancer was independently confirmed by groups from Lund, MDAnderson, and UNC (Sjodahl et al 2012; Choi et al 2014; Damrauer et al 2014). These systems partially overlap, and broadly speaking characterizes basal and luminal tumor subtypes (Fig. 135.16). The luminal group, characterized by high levels of *FGFR3,* GATA3, KRT20, and PPARG mutations was biologically less aggressive compared with the basal-squamous subtype, characterized by squamous differentiation, and expression of CK5, CK6, CK14, and low levels of FOXA1 and GATA3RNA and protein.

Ultimately, grouping bladder cancer into distinct molecular clusters may help identify certain patients that may benefit from specific therapies. For example, the MD Anderson classification identified a distinct subgroup of luminal tumors that they termed “P53-like”, that which were chemoresistant and associated with a poor prognosis (Choi et al., 2014). In addition, the UNC classification identified a claudin-low molecular subtype of MIBC enriched for RB1, EP300, and NCOR1, with decreased FGFR3, KDM6A, and PPARG amplification or expression. These claudin-low tumors are immune infiltrated and actively immune suppressed and may benefit from immune checkpoint inhibitors that have been FDA approved for the treatment of bladder cancer (Bai et al., 2016). **A 2017 follow-up study from the TCGA of 412 muscle-invasive tumors identified 5 expression subtypes that may stratify to different treatments** (Fig. 135.17). **In addition, that study identified a subset of patients with a high mutational load, driven by an APOBEC-mediated mutagenesis. APOEBEC comprises a family of cytidine deaminases that are involved in mRNA editing. This APOBEC related subset of patients had a 75% 5-year survival, far higher than the typical MIBC patient.**

Key Points

- Recent genome-wide expression and sequencing studies have identified genes and pathways that are clear drivers in urothelial cancer development.
- A molecular taxonomy is emerging broadly defined by urothelial cells types.
- The luminal phenotype is characterized by high levels of FGFR3, GATA3, KRT20, and PPARG mutations.
- The basal phenotype is characterized by squamous differentiation, and expression of CK5, CK6, CK14, and low levels of FOXA1 and GATA3 RNA and protein expression.

Histologic Variants of Urothelial Carcinoma

Urothelial carcinoma of the bladder had previously been labeled transitional cell carcinoma of the bladder because of its known propensity for cellular differentiation into other tumor types, such as SCC, adenocarcinoma, and clear cell carcinoma. Recently, a wider spectrum of histologic variants of urothelial cancer has been identified and investigated that includes distinct growth patterns of urothelial carcinoma, altered cellular differentiation of stromal reactions, and unique responses to treatment and external stimuli. The more common histologic variants are discussed here.

Micropapillary Variant

Micropapillary urothelial carcinoma was first described in 1994 and occurs in approximately 0.7% to 2.2% of all urothelial tumors (Amin et al., 1994; Johansson et al., 1999; Fig. 135.18). There is a strong male predominance associated with micropapillary urothelial cancer, with reports of a male-to-female ratio as high as 37:1. Micropapillary urothelial carcinoma is associated with advanced disease, as more than 50% are stage T3 or T4 at diagnosis; as such 5- and 10-year overall survival is 51% and 24%, lower than with other common histologies (Kamat et al., 2007). However, even among lower-stage bladder tumors, micropapillary variant is associated with a worse prognosis because these tumors are associated with a progression rate from non–muscle-invasive to muscle-invasive disease of 70%, with a high subsequent metastatic rate despite treatment (Kamat et al., 2007). Histologically, micropapillary urothelial carcinoma exhibit small tight clusters or thin papillae of atypical cells with eosinophilic to clear cytoplasm surrounded by prominent retraction artifact (Watts and Hansel, 2010). **Unlike other histologic subtypes, any amount of micropapillary urothelial carcinoma may be present for it to be defined as micropapillary and clinically managed as such.** The most effective therapy for all stages of micropapillary urothelial carcinoma is surgical resection. Treatment with transurethral resection and bacillus Calmette-Guérin therapy is ineffective unless the tumor is completely resected, and early cystectomy is encouraged for NMIBC, with a cancer-specific survival of 72% compared with 60% who undergo transurethral resection with intravesical BCG. Similarly, for muscle-invasive disease neoadjuvant chemotherapy does not appear to be effective, and immediate cystectomy is currently encouraged (Kamat et al., 2007). Molecular profiling of the micropapillary variant suggest that these tumors are characterized by ERBB2 amplification and activation of *miR-296* and *RUVBL1* target genes (Guo et al., 2016; Isharwal et al., 2018; Ross et al., 2014). The micropapillary variants appear to evolve almost exclusively through a luminal pathway, displaying enrichment of PPAR-gamma and suppression of *p63* genes. Similar to conventional luminal tumors, a subset of micropapillary cancers demonstrate activation of wild-type *p53,* and these represent the most aggressive phenotypes with the worst prognosis (Guo et al., 2016).

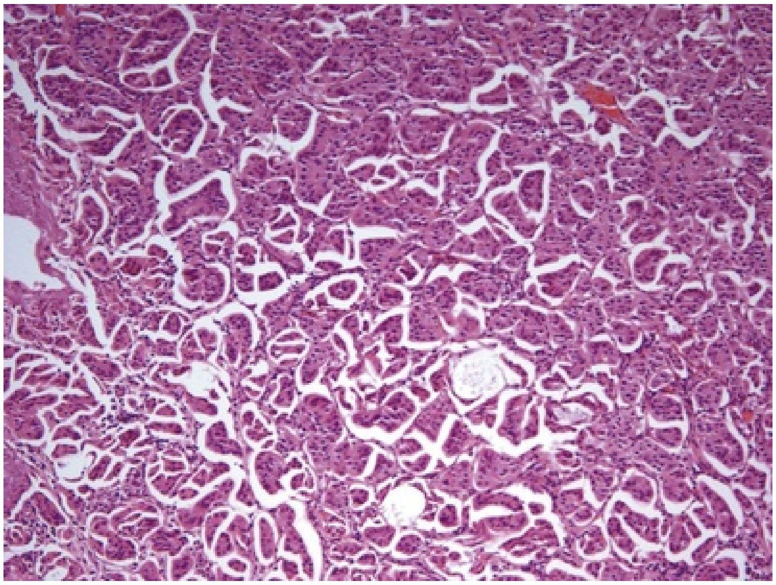

FIG. 135.18 Micropapillary urothelial cancer.

Sarcomatoid Variant

The sarcomatoid variant has a prevalence of 0.3% to 0.6% of all bladder cancers (Amin, 2009; Moschini et al., 2017a; Wright et al., 2007). Historically they were described separately as carcinosarcoma and sarcomatoid carcinoma, although molecular studies suggest that they have a common clonal origin (Armstrong et al., 2009; Gronau et al., 2002; Wright et al., 2007). Patients with the sarcomatoid variant are seen with large infiltrative masses, often at higher stages with a 5-year cancer-specific survival as low as 28.4% across all stages (Wang et al., 2010). Even when controlling for stage they have worse outcomes than pure urothelial tumors. These patients have a poor response to systemic chemotherapy, and thus immediate radical cystectomy is often considered when feasible; furthermore, our group and others have proposed intraoperative radiation therapy (IORT) at the time of radical cystectomy for these high-risk patients (Kates et al., 2017; Wang et al., 2010).

Plasmacytoid Variant

The plasmacytoid variant of urothelial carcinoma is rare, comprising less than 1% of all urothelial tumors (Lopez-Beltran et al., 2009; Moschini et al., 2017b). According to the 2016 WHO classification of urothelial carcinoma, plasmacytoid urothelial carcinoma now includes the signet ring variant, which is defined by the presence of cytoplasmic vacuoles with or without intracellular mucin. The plasmacytotic variant microscopically has increased eosinophilic cytoplasm, with eccentrically placed and enlarged hyperchromatic nuclei. These tumors typically are seen in an advanced stage with deep invasion into the bladder muscle and perivesical tissues, and with characteristic intraperitoneal metastatic spread. This aggressive phenotype is characterized by truncating somatic alterations in the *CDH1* gene, which occurs in 84% of cases according to one study (Al-Ahmadie et al., 2016). Although plasmacytoid variant is chemosensitive and thus treated with neoadjuvant chemotherapy whenever possible, relapses are common with median survival among non-metastatic patients just 17.7 months (Dayyani et al., 2013; Kaimakliotis et al., 2014; Ricardo-Gonzalez et al., 2012).

Nested Variant

The nested variant is a rare but aggressive cancer that has a male-to-female ratio of 6:1 and can be confused with benign lesions such as Von Brunn nests that are located in the lamina propria, cystitis cystica, and inverted papillomas (Fig. 135.19). Although the nested variant is typically upstaged at the time of cystectomy and found to be locally advanced at the time of presentation, stage-matched comparisons between nested variant and pure urothelial carcinoma suggest similar rates of recurrence and survival (Beltran et al., 2014; Linder et al., 2013).

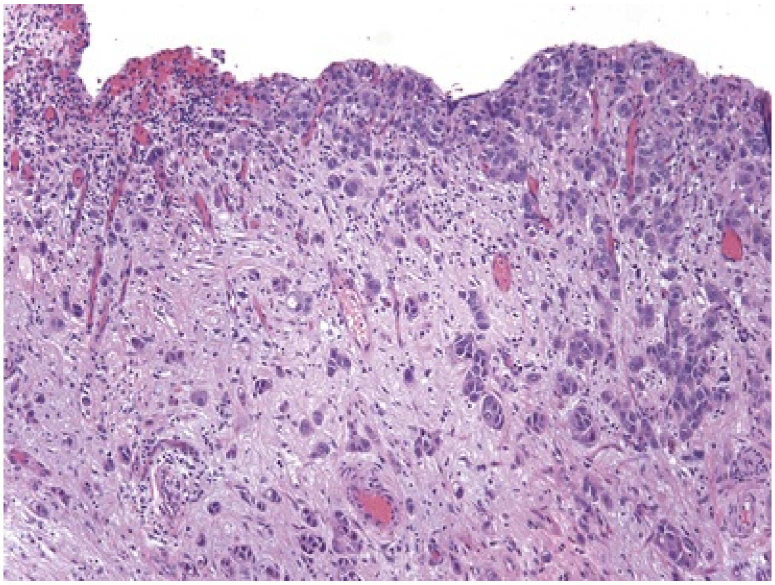

FIG. 135.19 Nested variant of urothelial cancer.

Urothelial Carcinoma With Divergent Differentiation

Urothelial carcinoma with squamous differentiation is present in up to 16% to 22% of patients with bladder cancer, although these may be underestimates, and studies suggest that up to 60% of bladder cancers have squamous elements (Black et al., 2009; Shanks and Iczkowski, 2009). The under-reporting of squamous differentiation and the percent of the tumor involved make it difficult to assess how this divergent histology affects clinical outcomes (Shah et al., 2013). Squamous differentiation is associated with the basal molecular subtype of bladder cancer, which is seen at a more advanced stage and is more focally aggressive (Choi et al., 2014). These tumors may be associated with recurrence and progression for patients with localized and advanced stages (Li et al., 2018; Minato et al., 2017).

Glandular differentiation comprises small tubular or gland-like spaces in otherwise conventional urothelial carcinoma and is present in approximately 10% of patients with urothelial bladder cancer. Similar to squamous differentiation, glandular differentiation is associated with a high stage at presentation and with clinical to pathological upstaging at the time of radical cystectomy; however, their clinical behavior does not appear to be different from conventional urothelial carcinoma, with similar rates of recurrence-free and overall survival (Kim et al., 2012; Mitra et al., 2014).

Nonurothelial Malignancy

Small Cell

Small cell carcinoma (Fig. 135.20) is a rare, poorly differentiated neuroendocrine neoplasm that primarily arises in the lung but can occur in extrapulmonary sites, including the prostate and bladder. Although patients typically are seen with hematuria, there have been reports of paraneoplastic syndromes associated with small cell carcinoma including hypercalcemia, Cushing syndrome, and sensory neuropathy. Small cell carcinoma of the bladder has a high somatic mutational burden driven by an APOBEC-mediated mutational process, and TP53, RB1, and TERT promoter mutations are frequently present (Chang et al., 2018). Evolutionary studies have suggested that small cell carcinoma of the bladder may represent a dedifferentiation from urothelial carcinoma, rather than having a shared lineage from small cell carcinoma of the lung.

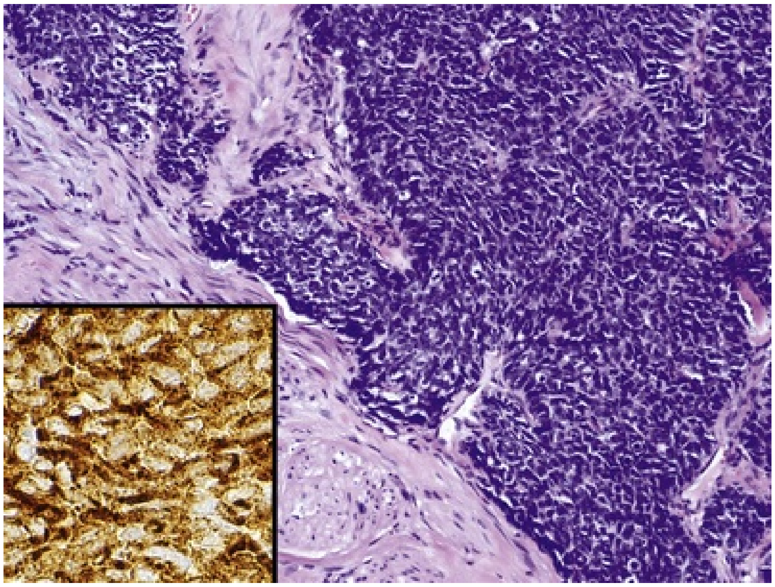

FIG. 135.20 Small cell carcinoma of the bladder. Tumor composed of sheets and nests of basophilic-appearing tumor cells with high nucleocytoplasmic ratio. Histologic features resemble small cell carcinoma seen in the lung. Tumor cells stain and show diffuse and strong immunoreactivity with neuroendocrine markers chromogranin *(inset)* and synaptophysin.

Small cell carcinoma of the bladder is clinically aggressive and chemosensitive. As such, platinum-based chemotherapy is recommended as the initial treatment regardless of the stage of presentation. A variety of chemotherapy regimens have been reported, but cisplatin and etoposide are the current treatment of choice based on the standard regimen for small cell carcinoma of the lung. Siefker-Radtke et al. (2004) reported that patients with primary small cell treated initially with cystectomy observed a 36% 5-year disease-free survival, which was not improved with adjuvant chemotherapy. However, patients who underwent neoadjuvant chemotherapy observed a cancer-specific survival of 78%. However, Kaushik et al. (2015) have demonstrated, in a separate study, that the aggressive features of small cell may be related to a high stage at diagnosis. Further, when matched stage-for-stage, small cell responds similarly to conventional urothelial carcinoma, and there may be a role for adjuvant chemotherapy. In addition, historically small cell was thought to be a nonsurgical entity and most appropriate for chemoradiation, whereas some groups still advocate for trimodal therapy. The combination of chemotherapy with cystectomy is associated with the highest response rates in published series, and further investigation into the safety of chemoradiation in small cell carcinoma is warranted (Bryant et al., 2016; Siefker-Radtke et al., 2004).

Squamous Cell Cancer

Chronic infection with *S. haematobium* or other bacteria leads to SCC of the bladder (Fig. 135.21). In countries with endemic schistosomiasis, SCC thus makes up the majority of bladder cancer and presents a unique growth pattern and treatment algorithm. In the United States and Europe SCC is more uncommon, occurring in 2% to 5% of all bladder cancers (Rausch et al., 2014). The central factor contributing to the development of SCC is chronic inflammation of the urinary tract. Historically patients with spinal cord injury requiring chronic catheterization had an incidence of SCC of 2.3%; however, this incidence rate has declined to 0.39% in contemporary series likely because of the trend toward intermittent self-catheterization. This supports the concept that chronic infection and foreign bodies can lead to bladder cancer formation. Data regarding the carcinogenesis of SCC are largely limited to schistosoma-induced SCC, detailed earlier in this chapter.

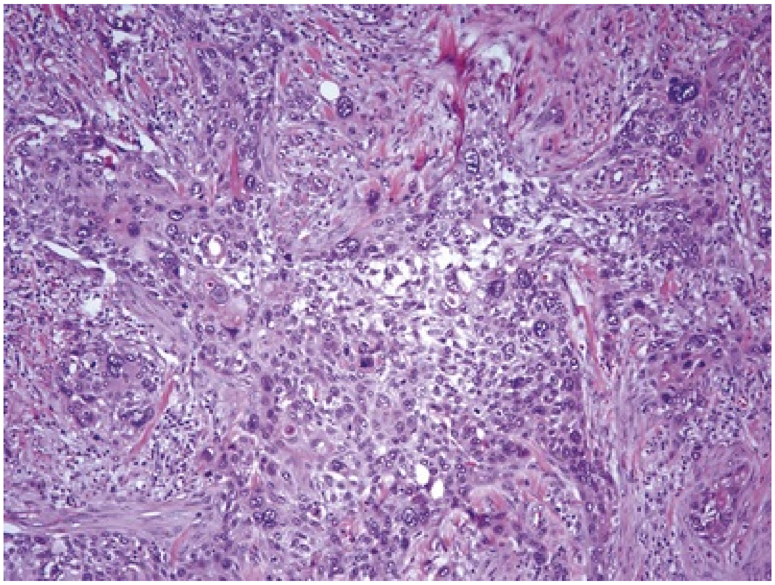

FIG. 135.21 Squamous cell cancer with associated urothelial cancer.

Despite having a lower incidence of nodal and metastatic disease, SCC often is seen initially at more advanced local stages than conventional urothelial carcinoma. Radical cystectomy is the mainstay treatment for SCC, and there is no clear consensus regarding the use of neoadjuvant chemotherapy before surgery. Preoperative radiation therapy was extensively studied in the 1970s and 1980s, but was associated with worse survival outcomes and thus should only be used if the patient is not undergoing cystectomy (Swanson et al 1990; Johnson et al 1976; Costello et al 1984). Adjuvant and intraoperative radiation therapy have also been proposed but there is no clear consensus on how or when it should be used. There is limited data regarding the molecular biology of SCC, particularly that which is not associated with schistosomiasis. Fibroblast growth factor (FGF2) has been shown to be associated with aggressive pathologic features and worse outcomes after radical cystectomy (Youssef et al 2015).

Adenocarcinoma

Adenocarcinoma (Fig. 135.22) may be a primary cancer arising from the bladder urothelium with a pure glandular phenotype, or may be a secondary cancer from a distant metastasis, or more commonly from direct extension from the colon, prostate, endometrium, or cervix. Although the urachus is not an anatomic component of the urinary bladder, urachal adenocarcinomas share similar pathologic and clinical features to bladder adenocarcinoma. Risk factors for adenocarcinoma are a history of bladder exstrophy, schistosomiasis, and chronic irritation or obstruction. Because secondary bladder adenocarcinomas are more common than primary adenocarcinomas, ruling out adenocarcinomas from other organs is recommended. At our center we have our patients undergo a colonoscopy whenever an adenocarcinoma is identified. Most primary bladder adenocarcinomas present with muscle invasive disease, and radical cystectomy is the standard treatment. Currently there is no level 1 data to support the use of chemotherapy or radiation therapy in the neoadjuvant or adjuvant setting. When chemotherapy is delivered the traditional MVAC or GC regimens used for conventional urothelial carcinoma are of little benefit. Often a regimen including 5-flourouracil and cisplatin is used based on experience with adenocarcinoma at other organ sites (Dadhania et al., 2015).

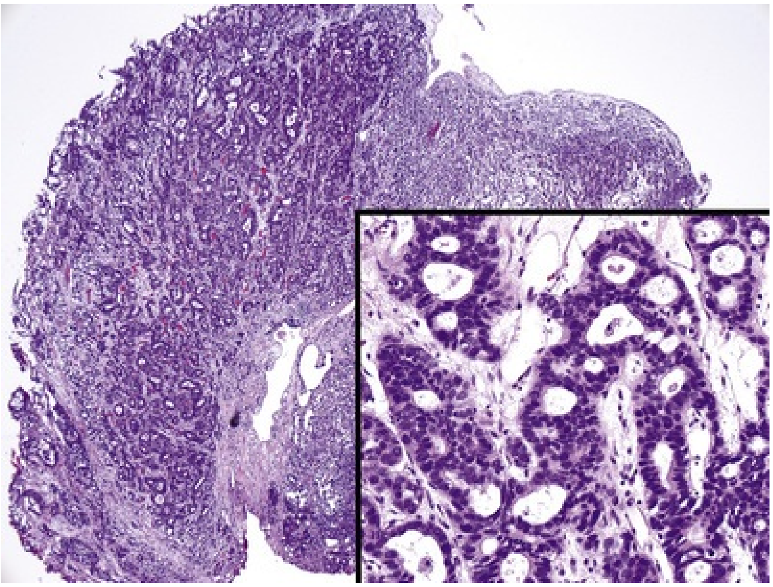

FIG. 135.22 Adenocarcinoma of the bladder. Transurethral resection of the prostate fragment showing extensive involvement by primary bladder adenocarcinoma. Note presence of cribriform and glandular architecture of tumor *(inset).*

Urachal Adenocarcinoma

Urachal adenocarcinoma is a rare cancer, accounting for approximately one-third of all bladder adenocarcinomas, that arises from the allantoic remnant that connects the bladder to the umbilical cord during embryogenesis. Although urachal remnants are typically lined by urothelial cells, urachal cancer is almost always adenocarcinoma in origin. The 2016 WHO classification introduced criteria for the diagnosis of urachal adenocarcinoma based on the work by Gopalan et al. (2009): the tumor should be located in the bladder dome or anterior abdominal wall, with the epicenter of the tumor occurring in the bladder wall; the tumor could not have widespread cystitis cystica, and there should be a thorough investigation for a secondary source for the adenocarcinoma. Urachal adenocarcinomas are difficult to stage using standard TNM staging because nearly all are muscle invasive because of their anatomic location. Staging of urachal carcinoma thus follows the system developed by Sheldon et al. (1984). Stage I tumors are carcinomas confined to the urachal mucosa, stage II tumors are confined to the urachus, stage III tumors are urachal tumors that extend locally into the bladder (IIIA), abdominal wall (IIIB), or peritoneum (IIIC), and stage IV tumors are metastatic (Sheldon et al., 1984). The standard treatment for urachal adenocarcinoma is en bloc resection of the bladder dome, urachal ligament, and umbilicus (Siefker-Radtke et al., 2003).

Key Points

- Eighty percent of urothelial carcinomas contain some mixed differentiation, most commonly squamous cell.
- Altered growth patterns, particularly micropapillary and nested variants, carry a poor prognosis, even for non–muscle-invasive disease.
- Neoadjuvant chemotherapy appears to be active in mixed tumors containing adenocarcinoma or squamous cell cancer but not against altered growth patterns such as in micropapillary and nested urothelial cancer.
- Small cell carcinoma of the bladder should be treated as metastatic disease with institution of chemotherapy followed by either radiation therapy or surgery for elimination of the local disease.

Management Strategies for Non–Muscle-Invasive Bladder Cancer (Ta, T1, and CIS)

Joseph Zabell MD, Badrinath R. Konety MD, MBA [a]

Non–muscle-invasive bladder cancer (NMIBC) is the term commonly applied to malignant urothelial tumors that have not invaded the detrusor muscle of the bladder (Epstein et al., 1998; Smith et al., 1999). This terminology encompasses the relatively benign course of low-grade papillary tumors, the more aggressive clinical course of high-grade tumors including urothelial carcinoma in situ (CIS), and high-grade Ta and T1 tumors. **Approximately 70% to 80% of bladder tumors are non–muscle invasive at presentation with 60% to 70% as stage Ta, 20% to 30% as T1, and approximately 10% as CIS** (Fig. 136.1) (Aldousari and Kassouf, 2010; Ro et al., 1992).

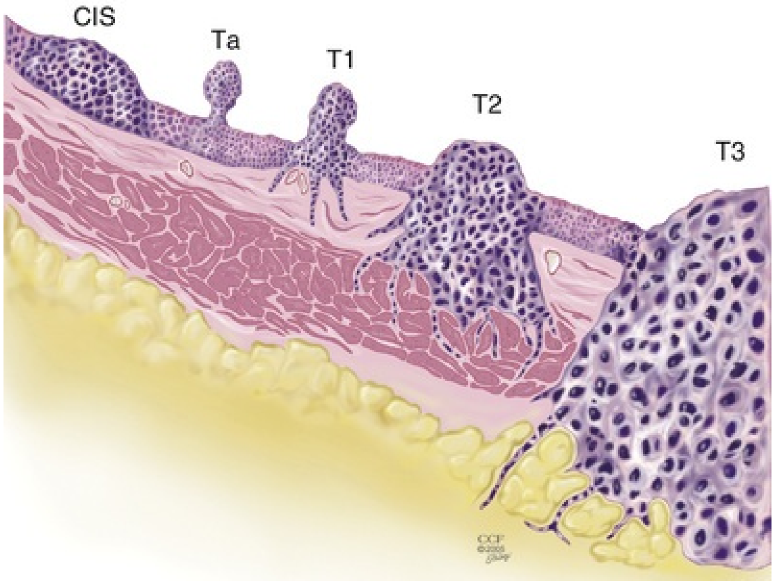

FIG. 136.1 Carcinoma in situ is a high-grade, flat malignancy confined to the urothelium. Papillary tumors confined to the urothelium are Ta, whereas papillary tumors invading lamina propria are T1. The T1 tumor here intertwines with the wispy fibers of the muscularis propria but by definition does not invade the smooth muscle fibers of the detrusor. T2 tumors invade the detrusor muscle, and T3 tumors are in extravesical fat as shown. *CIS,* Carcinoma in situ.

Painless hematuria (either visible or non-visible) is the most common presenting symptom of NMIBC. Patients with visible hematuria have reported rates of bladder cancer much higher than that observed in patients with non-visible (>3 RBC/hpf on microscopic urinalysis) hematuria (Tan et al., 2018)**. A recent prospective study of more than 3500 patients from 40 institutions found that 10.9% of patients with visible hematuria had bladder cancer, whereas non-visible hematuria was associated with bladder cancer in 2.5%** (Tan et al., 2018)**. Other studies have found a prevalence of bladder cancer in 0.3% to 4.7% of patients with non-visible or microscopic hematuria** (Kang et al., 2015; Khadra et al., 2000). Bladder cancer patients younger than 40 years are more likely to have visible hematuria rather than non-visible hematuria.

The degree of hematuria, whether visible or non-visible is not predictive of stage and grade of cancer (Tan et al., 2018). The **presence of irritative voiding symptoms in the absence of a urinary tract infection is also associated with CIS** with some studies reporting rates of up to 80% (Zincke et al., 1985). In a review of 600 patients diagnosed with interstitial cystitis, 1% of the patients had a missed diagnosis of urothelial carcinoma, although the majority of these patients did not have hematuria (Tissot et al., 2004). Thus **cystoscopy and upper tract imaging are indicated in patients with hematuria and/or unexplained irritative symptoms** (Davis et al., 2012; Grossfeld et al., 2001).

Recurrence is common in all patients with NMIBC but can often be managed with multimodal treatment, including transurethral surgery with or without intravesical immunotherapy and chemotherapy therapy. Risk of recurrence is typically approximately 40% to 60% but can be influenced by multiple clinical factors. Risk of progression, however, is of key concern in patients with NMIBC given the heterogeneity of tumors in this category with rates of progression as low as 6% in patients with low-grade Ta lesions (Leblanc et al., 1999) to as high as 17% in high-grade T1 tumors (Palou et al., 2012). The frequency of progression and death is shown in Table 136.1.

TABLE 136.1

Estimates of Disease Progression in Non–Muscle-Invasive Bladder Cancer: World Health Organization/International Society of Urologic Pathology Consensus Classification

TUMOR TYPE	RELATIVE FREQUENCY (%)	PROGRESSION (%)	DEATHS (%)
NONINVASIVE			
Papilloma	10	0–1	0
Papillary urothelial neoplasm of low malignant potential	20	3	0–1
Papillary cancer, low grade (TaG1)	20	5–10	1–5
Papillary cancer, high grade (TaG3)	30	15–40	10–25
INVASIVE			
Papillary cancer (T1G3)	20	30–50	33
CARCINOMA IN SITU			
Primary	10	>50	—
Secondary	90	—	—

From Donat SM: Evaluation and follow-up strategies for superficial bladder cancer. *Urol Clin North Am* 30:765–766, 2003.

Considerable work has been completed in an effort to develop clinical tools for risk stratification of patients with NMIBC. One previously published stratification system has been developed by the European Organization for Research and Treatment of Cancer (EORTC) with the goal of predicting probability of recurrence and progression at 1 and 5 years after treatment. Factors associated with recurrence include previous recurrence, number of tumors, and tumor size. For progression, significant factors for prognosis were T stage, presence of CIS, and grade (Sylvester et al., 2006). A similar model was developed by the Spanish Urological Club for Oncological Treatment/Club Urologico Espanol de Tratamiento Oncologico (CUETO) (Fernandez-Gomez et al., 2009). The EORTC model was limited by minimal use of bacille Calmette-Guérin (BCG) maintenance, perioperative mitomycin C (MMC), and restaging transurethral resection of bladder tumor (TURBT) in the patient cohorts used for model development. As a consequence, they tended to overestimate the rate of recurrence and progression. Using data from more recent trials incorporating patients who have received BCG maintenance therapy, the EORTC risk assessment tool has been updated (Cambier et al., 2016). However, the cohort is deficient in patients with CIS and requires further independent validation. More recently, the American Urological Association and Society of Urologic Oncology (AUA/SUO) Guideline for the Diagnosis and Treatment of Non–Muscle-Invasive Bladder Cancer has been published, which created a novel risk stratification schema (Table 136.2; Chang et al., 2016). Such risk stratification models allow for more nuanced evaluation of risk of recurrence and progression in patients with NMIBC, therefore allowing for risk-adapted treatment and surveillance strategies.

TABLE 136.2

American Urological Association Risk Stratification for Non–Muscle-Invasive Bladder Cancer

LOW RISK	INTERMEDIATE RISK	HIGH RISK
LG solitary Ta ≤ 3 cm	Recurrence within 1 year, LG Ta	HG T1
PUNLMP	Solitary LG Ta > 3 cm	Any recurrent, HG Ta
	LG Ta, multifocal	HG Ta, >3 cm (or multifocal)
	HG Ta, ≤ 3 cm	Any CIS
	LG T1	Any BCG failure in HG patient
		Any variant histology
		Any LVI
		Any HG prostatic urethral involvement

BCG, Bacille Calmette-Guérin; *CIS,* carcinoma in situ; *HG,* high grade; *LG,* low grade; *LVI,* lymphovascular invasion; *PUNLMP,* papillary urothelial neoplasm of low malignant potential.

Pathology: Grading and Staging

Pathological Staging

Tumor staging for urothelial carcinoma of the bladder is outlined by the American Joint Committee on Cancer (AJCC) criteria that include clinical and pathological staging outlines. Clinical stage reflects findings in TURBT as well as radiologic and physical exam findings with bimanual exam at time of TURBT. These findings allow the clinician to determine if lamina propria and/or muscularis propria are present or involved in the specimen and should assess for lymphovascular invasion (LVI), if possible. Pathological staging is based on surgical resection of the bladder via partial or radical cystectomy and pathological evaluation of pelvic lymph nodes.

The bladder has three main histologic layers: (1) urothelium, (2) suburothelial connective tissue called *lamina propria,* and (3) detrusor or muscularis propria (which is absent beneath the urothelium of diverticula). TNM staging for NMIBC includes noninvasive papillary tumors confined to urothelium regardless of grade (stage Ta), tumors invading the subepithelial tissue (lamina propria) (T1), and carcinoma in situ/tumor in situ (CIS/Tis). The TNM grading system is illustrated in Fig. 136.1.

Tumors invading the lamina propria can exhibit focal or extensive invasion. Several strategies have been used to sub-stratify T1 disease; extent of invasion is thought to correlate with progression to muscle-invasive disease (Leivo et al., 2018). One commonly used method includes evaluation of depth of invasion relative to the muscularis mucosae, which is a layer of discontinuous wispy bands of smooth muscle within the lamina propria. Tumors invading deep to the muscularis mucosae have been found to have a worse prognosis (Roubret et al., 2013). However, because of discontinuity of this layer and difficulty of orientation with some TURBT specimens, the depth of lamina propria invasion cannot be adequately assessed in all cases using this technique (Leivo et al., 2018). Recognition of the clinical importance of substaging of T1 tumors into T1a and T1b as part of the staging system has been proposed. The most recent *AJCC Staging Manual* emphasizes the importance of assessing the extent of lamina propria invasion; however, no specific approach to doing so is yet universally accepted (Amin et al., 2016).

Pathological Grading

Currently, the World Health Organization (WHO)/International Society of Urologic Pathology (ISUP) grading system from 2015 is widely accepted and commonly used (Moch et al., 2015). This system highlights the term *urothelial cancer* as being preferable to the previously common terminology of *transitional cell cancer*, although the former term is still occasionally used. Since the 2004 revised classification system was published, bladder cancer grade has been differentiated between low-grade tumors and high-grade tumors, rather than the previously published three-tiered WHO/Ash-Broder system. Currently used common classification includes hyperplasia (flat and papillary), reactive atypia, atypia of unknown significance, urothelial dysplasia, urothelial CIS, urothelial papilloma, papillary urothelial neoplasm of low malignant potential, non–muscle-invasive low-grade papillary urothelial carcinoma, and non–muscle-invasive high-grade papillary urothelial carcinoma.

Essentially benign papillary tumors with orderly cellular arrangement, minimal architectural abnormalities, and minimal nuclear atypia are distinct from those two grades and are designated papillary urothelial neoplasm of low malignant potential (PUNLMP), which are largely regarded as unlikely to progress and are considered essentially benign. However, on the basis of this low risk, the WHO recommends that such pathology reports contain the note, "Patients with these tumors are at risk of developing new bladder tumors ('recurrence'), usually of similar histology. However, occasionally these subsequent lesions manifest as urothelial carcinoma (UC), such that follow-up of the patient is warranted" (Epstein et al., 1998). Papillomas are truly benign and not associated with risk of progression (Figs. 136.2 through 136.5; also see Fig. 136.1).

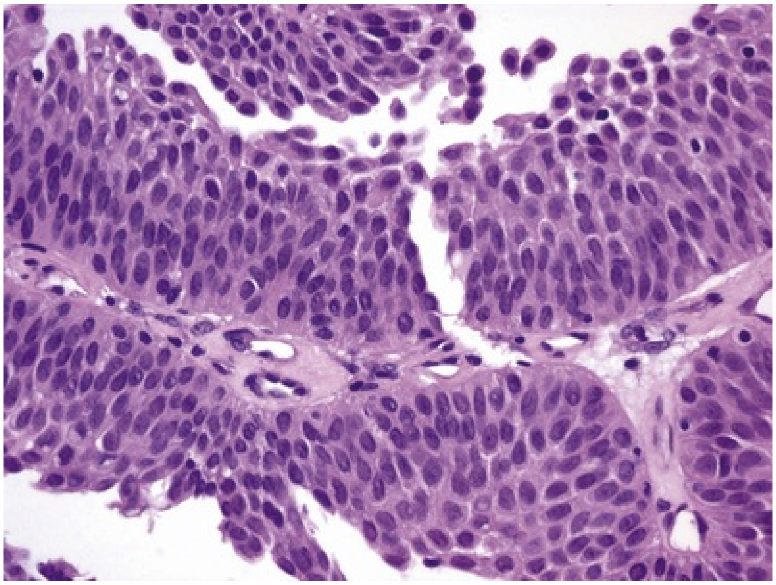

FIG. 136.2 The urothelium is thickened, but cells and nuclei are normal in papillary urothelial neoplasm of low malignant potential (×40).

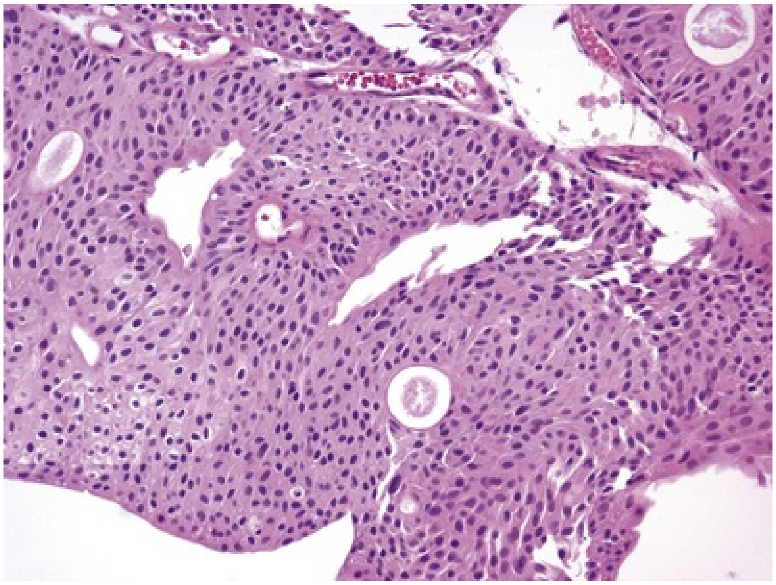

FIG. 136.3 Ta low-grade tumor (×40). Cells are relatively normal but exhibit irregularity and some nuclear differentiation.

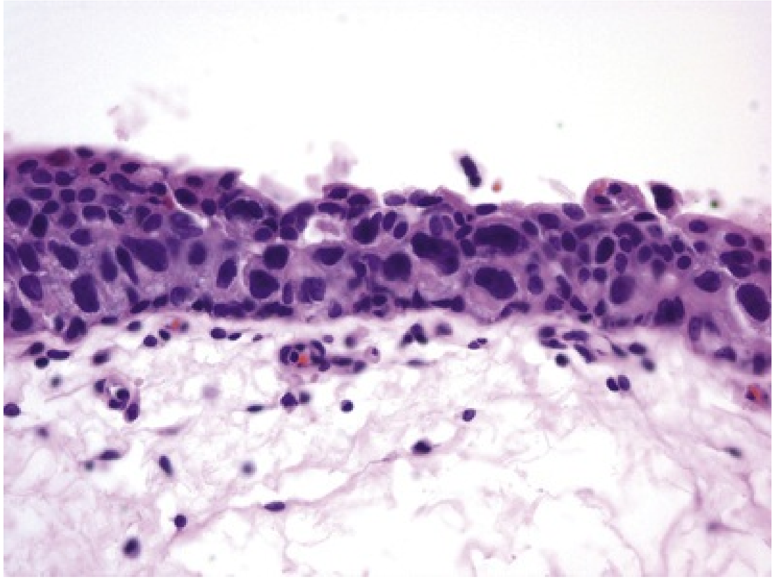

FIG. 136.4 Carcinoma in situ (×40) exhibits severe irregularity of cellular structure and nuclear pleomorphism, but there is no invasion of lamina propria.

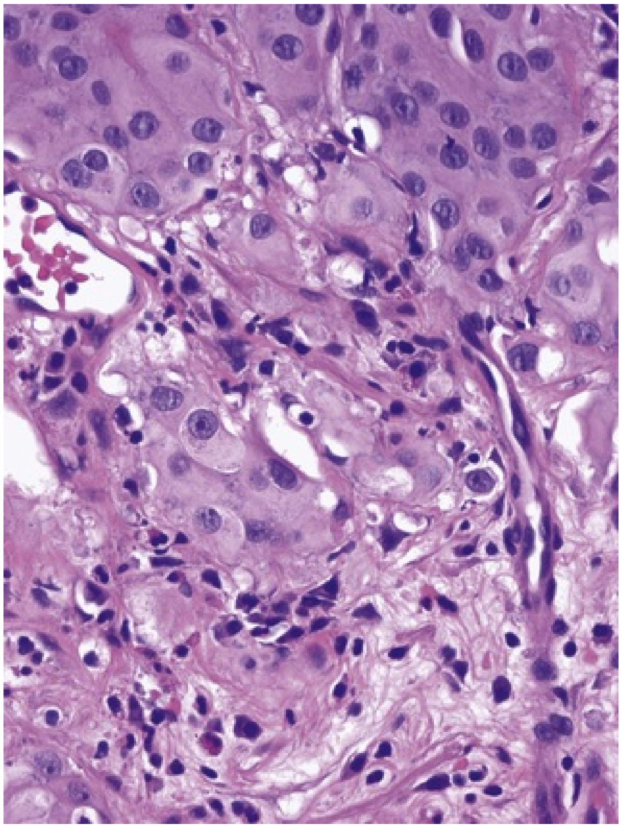

FIG. 136.5 T1 (×40) high-grade tumor exhibits nesting of abnormal cells and mitotic figures. Tumor cells can be seen invading the lamina propria in

the lower one-third of the photomicrograph.

Tumor Biology

Low-grade tumors and high-grade tumors have very different natural histories, consistent with grade being among the most important predictors of prognosis in NMIBC. **Low-grade Ta lesions recur at a rate of 50% to 70% and progress in less than 5% of cases. In contrast, high-grade T1 lesions recur in more than 80% of cases and progress in 50% of patients within 3 years.** This behavior is primarily grade dependent, rather than stage dependent: high-grade tumors progress with similar frequency regardless of whether they were invasive (T1) or noninvasive (Ta) (Herr, 2000b). **Prognosis also correlates with tumor size, multiplicity, papillary versus sessile configuration, presence or absence of lymphovascular invasion, and status of the remaining urothelium** (Althausen et al., 1976; Heney et al., 1983a, 1983b; Kunju et al., 2008; Lutzeyer et al., 1982).

The divergence in biologic behavior for low-grade versus high-grade lesions correlates with the known dual molecular lines of genetic development for these two pathways and supports the concept that **high-grade and low-grade cancers may essentially be considered different diseases** (Droller, 2005; Hasui et al., 1994). **Chromosomal alterations caused by oxidative DNA damage create two separate genetic pathways to the development of UC** (Cote and Chatterjee, 1999; Richter et al., 1997; Spruck et al., 1994). The first and more common (low grade) leads to noninvasive, papillary tumors. These usually follow an indolent course unless they convert to or are associated with a secondary tumor of a second higher-grade pathway (Kiemeney et al., 1993). Fibroblast growth factor receptor 3 *(FGFR3)* mutations, along with chromosome 9 deletions occur in the majority of papillomas and low-grade tumors and are related to the RAS pathway and cell proliferation (Wolff et al., 2005).

The second pathway leads to the development of high-grade cancer, including CIS, T1, and, ultimately, muscle-invasive carcinoma. Such genetic alterations can be evaluated using karyotyping, microsatellite analysis for allelic imbalance (Mao et al., 1996), comparative genomic hybridization (Kallioniemi et al., 1995), DNA ploidy analysis by flow cytometry (Bittard et al., 1996), and fluorescence in situ hybridization (FISH) (Degtyar et al., 2004). High-grade tumors tend to have numerous and greatly variable chromosomal gains and losses. In addition to their relatively predictable aneuploidy, high-grade tumors can also lose all or part of chromosome 9 (Richter et al., 1997). Although almost any chromosome can be affected, aneuploidy of chromosomes 7, 9, and 17 is associated with especially aggressive tumors (Degtyar et al., 2004; Olumi et al., 1990; Waldman et al., 1991). Specific mutations have been linked to risk of progression, including p53, p21, and pRb, which act in cooperative and synergistic ways to promote bladder cancer progression (Chatterjee et al., 2004).

Because of these differing genetic imprints, it has been suggested that papillary pTa tumors could almost be considered benign and may be a completely separate disease entity in contrast to high-grade tumors (Harnden, 2007; Sauter and Mihatsch, 1998). Nevertheless, high-grade and low-grade lesions are known to coexist. UC is traditionally considered a field change disease, with tumors arising at different times and sites. Rarely, patients who initially have low-grade tumors subsequently develop high-grade tumors, often years after the original tumors, so long-term surveillance is usually appropriate (Holmäng and Ströck, 2012).

Pathological Characteristics by Stage and Implications for Clinical Management

Stage Ta tumors are usually low grade. Although recurrence is common, especially in the setting of multiplicity, progression is rare. However, **2.9% to 18% of Ta tumors are high grade, with an average of 6.9%** (Sylvester et al., 2005). **The most important risk factor for progression is grade, not stage** (Millán-Rodríguez et al., 2000; Sylvester et al., 2005).

CIS is occasionally mischaracterized as "premalignant" (Sylvester et al., 2005), **but it is actually a flat, noninvasive UC that is high grade by definition and is regarded as a precursor to the development of invasive high-grade cancer.**

CIS lesions are composed of severely dysplastic urothelium. Microscopically, tumors demonstrate disorderly histology with nuclear atypia characteristic of high-grade malignancy; denudement of some or all of the mucosa as a result of loss of cellular cohesion sometimes complicates interpretation. A pathology report read as dysplasia or atypia can create confusion. Most pathologists consider mild examples of these entities to be benign. However, **lesions interpreted as severe/high-grade dysplasia are regarded as being the same entity as CIS** (Epstein et al., 1998).

From 40% to 83% of patients with CIS develop muscle invasion if

untreated, especially if associated with papillary tumors (Althausen et al., 1976). Among patients thought to have CIS alone, up to 20% who are treated with cystectomy are found to actually contain invasion on final pathology (Shariat et al., 2006). The presence of CIS in specimens from cystectomy performed for presumed T1 tumors was associated with upstaging in 55% of patients in one series, compared with 6% upstaging in patients without CIS (Masood et al., 2004). In a series of 1500 patients, CIS was the second most important prognostic factor after grade (Millán-Rodríguez et al., 2000). Multicentricity presents another ominous characteristic of CIS (Koch and Smith, 1996). The presence of irritative voiding symptoms has been associated with diffuse disease, invasion, and a compromised prognosis, but there is no consensus on this finding in the literature (Smith et al., 1999; Sylvester et al., 2005). The incidence of node-positive disease in patients with CIS only who undergo radical cystectomy can be up to 3% (Shariat et al., 2006).

T1 tumors are usually papillary and often have a narrow stalk; a **nodular or sessile appearance suggests deeper invasion. Deep penetration into the lamina propria, especially if involving muscularis mucosae, increases the risk of recurrence and progression in some reports. Lymphovascular invasion** (Kim et al., 2014; Streeper et al., 2009; Tilki et al., 2013), **pyuria** (Azuma et al., 2013), **and bladder neck involvement** (Kobayashi et al., 2014) **also increase this risk. Hydronephrosis often indicates muscle invasion.**

There is significant potential for understaging in patients with high-grade, apparently non–muscle-invasive tumors, especially those that appear to be stage T1. At time of cystectomy many tumors are found to be more extensive than what was indicated by the transurethral resection (TUR) specimen. Understaging errors ranging from 34% to 62% have been reported (Stein et al., 2001). Herr (1999) reported considerable rates of upstaging tumors on restaging TURBT of high-grade tumors, particularly T1 tumors where up to 49% of tumors were found to be muscle invasive on restaging TURBT. Studies addressing the risk of understaging of T1 tumors are shown in Table 136.3. These data highlight the importance of performing a more thorough second resection to accurately estimate the depth of invasion and reduce the likelihood of missing T1 tumors that are actually muscle invasive. This is particularly important in patients with absence of muscle in the initial resection specimen.

TABLE 136.3

Risk of Understaging When Cystectomy Is Performed for Presumed Non–

Muscle-Invasive Disease

STUDY	INSTITUTION	RISK (%) OF UNDERSTAGING
Stein et al., 2001	Southern California	39
Dutta et al., 2001	Vanderbilt University	40
Bianco et al., 2004	Wayne State University	27
Bayraktar et al., 2004	Vakif Gureba Hospital, Aksaray-Istanbul, Turkey	50
Huguet et al., 2005	Servicio de Urologia, Fundació Puigvert, Barcelona	27
Ficarra et al., 2005	University of Verona, Italy	43

Key Points: Pathology

- Malignant tumors are classified as low grade or high grade, regardless of invasion.
- High- and low-grade cancers are often considered essentially separate diseases based on disparate genetic development, biologic behavior, and management strategies.
- The most important risk factor for progression is grade.
- CIS is a precursor as well as a risk factor for progression, invasion, and metastasis.
- Papillary tumors with orderly cellular arrangement, minimal architectural abnormalities, and minimal nuclear atypia are designated PUNLMP.

Endoscopic Surgical Management

Procedures

Upon the identification of a bladder tumor during office-based cystoscopy, the location, number, and morphology of tumors are recorded, as is involvement of areas likely to reflect extravesical extension such as the ureteral orifices and bladder neck or prostatic urethra. Urinary cytology is typically obtained as a baseline and to establish the likelihood of high-grade disease. Positivity will encourage random bladder biopsy at the time of TUR, as discussed later.

Cross-sectional imaging to evaluate the upper urinary tract such as CT urography (Fig. 136.6) is commonly performed before TUR to identify other sources of hematuria and to assess the extravesical urothelium given the risk of concomitant upper tract disease secondary to the "field change" nature of UC, which can affect such tissue throughout the urinary tract**.** Retrograde pyelography or ureteroscopy can be planned for any upper tract abnormalities identified. CT urography, MR urography, or retrograde pyelography are typically used to evaluate for upper tract lesions, with ureteroscopy reserved for suspicious findings. Expert consensus is that patients with solitary or limited low-grade Ta lesions do not need upper tract imaging except at baseline because of the very low risk of extravesical disease (Chang et al., 2016; Davis et al., 2012; Goessl et al., 1997). The overall risk of identifying upper tract lesions in patients with known history of bladder cancer is low, and upper tract tumors occur in less than 5% of such patients. However, tumors at the trigone, the presence of concomitant CIS, and identification of high-risk disease are risk factors for the presence of upper tract disease (Millán-Rodriguez et al., 2000; Palou et al., 2005).

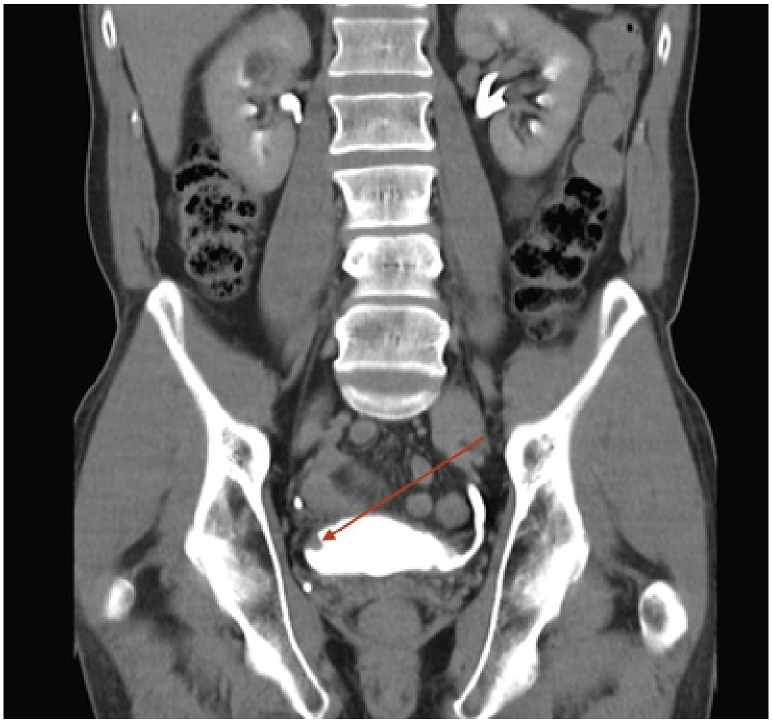

FIG. 136.6 CT urogram demonstrating a bladder tumor along the right lateral wall *(red arrow),* ultimately found to be a high-grade Ta bladder tumor.

TURBT under regional or general anesthesia is the initial treatment for visible lesions. This therapy is intended to be diagnostic and therapeutic by providing specimens to allow for pathological determination of stage and grade, while simultaneously removing and/or fulgurating all visible tumors. Bimanual examination of the bladder is often performed with the patient under anesthesia before preparation and draping and is repeated after resection to allow for appropriate clinical staging. Fixation or persistence of a palpable mass after resection suggests locally advanced disease, although the additional value of this maneuver in the era of modern imaging appears limited and may even be misleading (Ploeg et al., 2012).

Complete visualization of the bladder should be completed using a flexible cystoscope and/or the 30- and 70-degree rigid lens. Resection is typically performed using continuous flow **irrigation and resectoscope with the bladder filled only enough to visualize its contents. This minimizes bladder wall movement and lessens thinning of the detrusor through overdistention, thereby reducing the risk of perforation** (Koch and Smith, 1996). An outflow suction can be used, which allows for more refined control of bladder volume and avoids inadvertent overdistention, which could result in extravasation through microperforations in the bladder wall. Resection is performed piecemeal, delaying transection of tumor base or stalk until the majority of tumor burden has been resected. **Friable, low-grade tumors can often be removed without the use of electrical energy** because the non-powered cutting loop will break off such tumors. This minimizes the chance of bladder perforation and unnecessary cautery damage or loss of specimens. Higher grade, more solid tumors and the base of all tumors require the use of cutting current; cautery yields hemostasis once the entire tumor has been resected. **Lifting the tumor edge away from detrusor lessens the chance of perforation** (Holzbeierlein and Smith, 2000). There appears to be variability in completeness of resection among surgeons as demonstrated by previous data demonstrating variability in recurrence rates from 7.4% to 45.8% depending on the surgeon (Brausi et al., 2002).

After all visible tumor has been resected, an additional pass of the cutting loop or a cold-cup biopsy can be obtained to send to pathology separately to determine the presence of muscle invasion of the tumor base. An Ellik or similar chip evacuator can be used to gather the chips floating in the bladder, and final confirmation of hemostasis should be assessed in the presence of minimal irrigation after all chips have been removed.

Traditionally, TUR has been performed using sterile water because saline solutions conduct electricity and disperse energy from the monopolar cautery cutting loop. Bipolar energy, as opposed to monopolar energy, appears to offer some advantages. In a systematic review, Zhao et al. (2016) found that patients undergoing TUR with bipolar energy had shorter hospital stay, less blood loss, and fewer complications such as obturator reflex and bladder perforation. **The use of bipolar cautery allows use of saline irrigation,** which can decrease risk of TUR syndrome in cases of perforation and if the resection is prolonged. Data suggest that tissue preservation for pathological evaluation is at least as good as with monopolar resection, if not better. The use of general anesthesia with muscle-paralyzing agents also prevents obturator reflex in patients with tumors along the posterolateral bladder walls.

Resection of diverticular tumors presents significant risk of bladder wall perforation, and accurate staging is difficult to achieve given the absence of underlying detrusor. Invasion beyond the diverticular lamina propria immediately involves perivesical fat (stage T3a by definition). Resection in diverticula frequently leads to bladder perforation. **Low-grade diverticular tumors are best treated with a combination of conservative resection and**

fulguration of the base. This can be followed by subsequent repeat resection if the final pathological interpretation is high grade. High-grade tumors require adequate sampling of the tumor base, often including perivesical fat, despite the near certainty of bladder perforation. In such cases, an indwelling catheter should be left for several days to allow for urothelial healing. **Partial or radical cystectomy should be strongly considered for high-grade diverticular lesions because tumors can penetrate extravesically with relative ease given the lack of a muscularis layer in the diverticula.**

Anterior wall tumors and tumors at the dome in patients with large bladders can be difficult to reach. Minimal bladder filling combined with manual compression of the lower abdominal wall to bring the tumor toward the resectoscope facilitates removal. Extra-long resectoscopes available from many manufacturers are long enough to reach the entirety of most bladders. Rarely, the creation of a temporary perineal urethrostomy can be used to allow for better access, particularly in the obese patient with an anterior wall or dome tumor. Digital manipulation through the rectum or vagina or downward compression of the suprapubic area can occasionally facilitate resection.

Care must be taken during resection near the ureteral orifice to prevent obstruction from scarring after fulguration. **Pure cutting current causes minimal scarring and may be safely performed, including resection of the orifice if necessary.** Resection of the intramural ureter may lead to complete eradication of some tumors but risks reflux of malignant cells. The clinical implications of this are unclear (Palou et al., 1992).

As an alternative to formal TURBT, **many small tumors may be resected using the cold-cup biopsy forceps** alone. This is especially helpful in patients with thin-walled bladders, such as can be seen in elderly females, because of risk of perforation with traditional transurethral resection techniques. If perforation does occur in this circumstance, the biopsy forceps typically leads to a smaller perforation than the cutting loop, facilitating subsequent healing. A Bugbee cauterization electrode facilitates hemostasis.

En bloc resection of bladder tumors represents another alternative, relatively novel resection technique that can be performed with the traditional loop electrode, Hybrid-Knife, holmium laser, Thulium laser, or KTP laser (Kramer et al., 2015, 2017). This technique involves excision of the entire tumor with underlying segment of muscle with the specimen being resected and extracted intact, rather than piecemeal. The benefit of this derives from less cautery artifact, thereby allowing more accurate assessment of muscle invasion by pathology. This technique is most feasible in papillary tumors with a distinct stalk; however, specimen extraction after en bloc resection may become problematic in the case of large tumors, which may require fragmentation into pieces to allow extraction through the resectoscope. Because of this potential difficulty, it is thought that up to a third of tumors are not amenable to en bloc resection given tumor size or location. Further potential disadvantages of this technique include possible disruption of tissue at incision line, equipment acquisition costs, and risk of excessive tissue penetration depth (Kramer et al., 2017). Regardless, en bloc resection provides a viable approach to intravesical management of appropriately selected tumors. ▶Video 136.1 demonstrates this technique.

If a tumor appears to be muscle invasive, biopsies of the borders and base to establish invasion may be performed in lieu of complete resection, given the likelihood of subsequent cystectomy. Failure to demonstrate invasion necessitates repeat resection unless the decision is made to proceed to cystectomy based on factors other than muscle invasion. Using a 10-item checklist that meticulously documents all the important elements of the TUR can enhance adequacy of specimen that is obtained and the thoroughness of resection (Anderson et al., 2016).

Complications of Transurethral Resection of Bladder Tumor and Bladder Biopsy

Minor bleeding and irritative symptoms are common side effects in the immediate postoperative period. The major complications of uncontrolled hematuria and clinical bladder perforation occur in 1% to 6.7% of cases (Comploj et al., 2014), although up to 50% of patients can exhibit contrast agent extravasation indicative of minor perforation if cystography is performed (El Hayek et al., 2009). Perforations tend to occur in elderly patients with large posterior wall tumors, particularly in cases involving previous treatment with multiple courses of intravesical therapy (Golan et al., 2011). The incidence of perforation can be reduced by attention to technical details, avoiding overdistention of the bladder, and using anesthetic paralysis during the resection of significant lateral wall lesions to lessen an obturator reflex response. Moreover, large, bulky tumors and those that appear to be muscle invasive are often best resected in a staged manner because it is believed that repeat resection can more safely remove residual tumor if indicated.

The majority of perforations are extraperitoneal; however, intraperitoneal rupture is possible when tumors are resected at the dome (Collado et al., 2000)**. The risk of tumor seeding from perforation appears to be low** (Balbay et al., 2005). However, anecdotal reports have identified extravesical recurrences after perforation, theoretically caused by seeding (Mydlo et al., 1999). It has been suggested that the risk of tumor seeding is higher in patients who undergo surgical repair, but this may be related to patient selection because only serious intraperitoneal perforations are likely to be managed in this manner (Mydlo et al., 1999; Skolarikos et al., 2005). **Bladder perforation during TUR does appears to be associated with greater risk of recurrence and worse disease-free survival in a series published by Comploj et al.** (2014)**. However, neither cancer-specific nor overall survival were affected in this series because these patients were more likely to undergo radical cystectomy.**

Extraperitoneal bladder perforation during TURBT can typically be managed with prolonged urethral catheter drainage. Intraperitoneal perforation is less likely to close spontaneously and usually requires open or laparoscopic surgical repair. Decisions for surgical correction should be made on the basis of the extent of the perforation and the clinical status of the patient. On occasion, a frozen section of the resected specimen can be performed and if there is clear evidence of muscle invasion, a cystectomy could be advised in lieu of closure of bladder perforation. Open repair of an intraperitoneal perforation or cystectomy will also allow for more thorough washout of the abdomen to potentially reduce the likelihood of local seeding from extravasated tumor.

TUR syndrome from fluid absorption is uncommon, particularly with the use of bipolar energy, and managed in the same manner as during transurethral resection of the prostate (TURP).

As long as resection of the ureteral orifice is performed with pure cutting current, scarring is minimal and obstruction unlikely. Cystoscopy to visualize efflux, which can be aided by intravenous administration of indigo carmine or methylene blue or retrograde ureteropyelography, can aid in determination of potential obstruction. In tumors that are close to the ureteral orifice, placement of an open-ended ureteral catheter before resection will help avoid encroachment of the orifice during resection. If fluorescence cystoscopy is in use as described later, the urine jet will appear green and can thus be visualized as well. If the orifice is resected or coagulation current is used nearby, renal ultrasonography in the postoperative period can aid in identification of asymptomatic obstruction. In one series, risk of ureteral stricture formation was rare at approximately 4% after TUR of the ureteral orifice, and most cases of hydronephrosis either resolved spontaneously or were associated with invasive disease (Mano et al., 2012). Balloon dilation of the orifice or endoscopic incision can relieve obstruction, but failure to respond will occasionally necessitate reimplantation (Chang et al., 1989).

Repeat Transurethral Resection of Bladder Tumor

Complete tumor removal is not always possible, whether as a result of excessive tumor volume, anatomic inaccessibility, medical instability requiring premature cessation of initial resection, or risk of perforation. It is important to obtain adequate muscle in the biopsy specimen to evaluate muscle invasion, particularly in cases in which T1 disease is identified or invasive tumor is suspected. This may also be important for high-grade tumors, although that seems to be less critical. The AUA and the EAU guidelines recommend obtaining muscle for evaluation by performing a second TUR if necessary in cases of incomplete resection, if no muscle is present in the initial specimen and in high-grade T1 tumors, although more emphasis is placed on this approach for T1 tumors (Babjuk et al., 2017; Chang et al., 2016).

Incomplete initial resection is often noted in such circumstances, as evidenced by data suggesting that tumors are noted at the first cystoscopic evaluation in up to 45% of patients (Brausi et al., 2002) and that residual tumor is identified at the site of the initial resection at least 40% of the time when repeat TUR is performed within several weeks of original resection (Klan et al., 1991; Mersdorf et al., 1998; Vogeli et al., 1998). In a review, Miladi et al. (2003) found that a second TURBT detected residual tumor in 26% to 83% of patients and corrected clinical staging errors in half of those patients.

In the case of high-risk, high-grade Ta tumors, multiple series suggest that residual tumor can be identified in up to 50% of cases (Grimm et al., 2003; Herr, 1999), and upstaging is noted in up to 15% of patients on repeat TURBT (Vianello et al., 2011). Given these findings, AUA guidelines recommend consideration of repeat TURBT of the primary tumor site within 6 weeks of initial TURBT in the setting of high-risk, high-grade Ta tumors (Chang et al., 2016).

In the setting of high-grade T1 tumors, repeat TURBT is recommended

within 6 weeks of initial TURBT based on the well-established risk of identifying worse prognostic findings or upstaging to muscle-invasive disease in up to 25% to 30% of repeat TURBT specimens (Herr, 2015; Schwaibold et al., 2000). **This is especially important if no muscle is identified on initial pathology, where repeat resection of patients with T1 disease can identify upstaging to muscle-invasive disease in up to 49% of cases** (Herr, 1999). Understaging is much more likely in T1 tumors when muscle is absent compared with when muscle is present in the specimen (64% vs. 30%) (Dutta et al., 2001). Herr (1999) reported that a second resection changed treatment in one-third of patients. Survival was 63% in patients who underwent a second TURBT versus 40% for those who did not in a German observational study (Grimm et al., 2003), and recurrences appear to be lower after repeat TUR (Sfakianos et al., 2014). Randomized data have also demonstrated that patients with T1 disease at initial resection who undergo a second TUR demonstrate lower rates of recurrence and progression (Divrik et al., 2010). Furthermore, the efficacy of BCG in preventing recurrence and progression appears to be higher in patients with high-grade papillary tumors and CIS if a restaging TURBT was performed before instillation of BCG (Herr, 2005). Finally, if residual stage T1 is noted on repeat TURBT, risk of progression has been demonstrated to be as high as 80% (Herr et al., 2007), thereby suggesting potential benefit of early cystectomy in these patients.

Repeat resection also is helpful in the setting of a second opinion, unless clear evidence of muscle invasion is identified on the initial resection, especially if the outside pathology slides are not available for review. In addition, subspecialty pathological reinterpretation at the time of second opinion can yield information, potentially leading to a change in management in almost one-third of patients (Lee et al., 2010).

In summary, given the data presented earlier, patients with stage T1 tumors merit repeat TUR. Patients with no muscle present in the initial specimen appear to benefit most in terms of recurrence, progression, and cancer-specific and overall survival (Gontero et al., 2016). As such, **AUA guidelines recommend repeat TURBT of primary tumor site, to include muscularis propria, within 6 weeks of the initial TURBT in patients with incomplete initial resection, and patients with stage T1 disease. These guidelines also recommend consideration of repeat TURBT in patients with high-risk, high-grade Ta tumors** (Chang et al., 2016).

Random Bladder Biopsies

Biopsies of any suspicious areas are an important part of a complete evaluation. Cold-cup biopsies may not provide as much information regarding muscular invasion but provide tissue sampling without cautery artifact (Smith, 1986; Soloway et al., 1978).

The use of random biopsies to identify CIS in otherwise normal-appearing mucosa remains controversial. May et al. (2003) performed random biopsies in high-risk patients and found that the results were positive in 12.4% and altered treatment in 7%, including 14 of 1033 patients in whom the only positive tissue was in the random biopsy specimen, rather than the primary resected tumor. However, even when velvety red patches were sampled, only 11.9% of biopsy specimens were positive in one report (Swinn et al., 2004). A European Organisation for Research and Treatment of Cancer (EORTC) retrospective review found that 10% of random biopsy specimens were positive (3.5% CIS) and concluded that such biopsies were not warranted (van der Meijden et al., 1999). Fujimoto et al. (2003) prospectively evaluated the role of random biopsies of normal-appearing urothelium and found cancer in only 8 of 100 biopsy samples, 5 of which were CIS. They concluded that random biopsies are indicated only in the setting of multiple tumors or positive cytology. **The current consensus is that random biopsies are not indicated in low-risk patients** (i.e., those with low-grade papillary tumors and negative cytology), but there remains no consensus with regard to patients with high-grade disease, and many urologists perform random biopsies in this setting particularly if urine cytology is positive.

Prostatic urethral biopsy using the cutting loop may be performed, especially if neobladder creation is anticipated for high-risk disease, but bleeding may be more common (Holzbeierlein and Smith, 2000). The additional value of the information obtained from cold-cup and or loop resected urethral biopsies must be weighed against the theoretic risk that such biopsies provide an exposed bed to aid tumor implantation (Kiemeney et al., 1994; Yamada et al., 1996). **Traditional teaching is that TURP and TURBT of a low-grade bladder tumor may be performed at the same setting but that resection of a high-grade bladder tumor should not be performed coincident to TURP to avoid tumor seeding and possible intravasation of tumor cells** likely to metastasize. Despite anecdotal reports of low-grade tumors implanting in the prostatic urethra after simultaneous resection, this risk appears to be small (Tsivian et al., 2003).

Laser Resection

Laser coagulation allows minimally invasive ablation of small papillary tumors up to 2.5 cm. The neodymium : yttrium-aluminum-garnet (Nd : YAG) laser has the best properties for use in bladder cancer. **The most significant complication of laser therapy is forward scatter of laser energy to adjacent structures, resulting in perforation of a hollow, viscous organ such as overlying bowel.** This is rare but more commonly occurs with the Nd : YAG laser because of its deeper tissue penetration than with holmium (Ho):YAG and potassium titanyl phosphate (KTP) lasers (Smith, 1986). Unless higher energy is necessary for a very large tumor, **limiting energy to 35 W precludes exceeding 60°C on the outer bladder wall, minimizing the risk of perforation** (Hofstetter et al., 1994).

Laser therapy can be more expensive than resection because of the cost of laser fibers, but bleeding is negligible and there is no risk of obturator reflex. More recently en bloc resection of bladder tumors (EBRT) has been accomplished using a Thulium laser. Tumors from 1 to 5 cm have been resected using this technique, and it appears to be safe and comparable with standard electrical TUR with low incidence of bleeding and bladder perforation (Kramer et al., 2015). A systematic review of the literature has identified that en bloc resection provides more than 95% rates of detrusor muscle in specimen, allowing for high-quality pathological evaluation with similar perioperative morbidity and recurrence rates to conventional TURBT (Kramer et al., 2017).

Office-Based Endoscopic Management

Many patients with small (typically <0.5–1 cm), low-grade recurrences can be managed safely in the office setting with use of diathermy or laser ablation (Donat et al., 2004). Instillation of viscous or injectable 1% to 2% lidocaine mixed with bicarbonate through a catheter and a dwelling time of 15 to 30 minutes yields mucosal analgesia, although pain with fulguration of 1- to 5-mm tumors is often acceptable without analgesia. A prior tissue diagnosis and a negative cytology for the initial tumor occurrence are mandatory to determine whether the tumor is of high or low grade.

In addition, **many small, low-grade tumors can be safely observed until they exhibit significant growth because of the minimal risk of progression** (Pruthi et al., 2008; Soloway et al., 2003).

Enhanced Cystoscopic Techniques: Fluorescence Cystoscopy, Narrow Band Imaging, Optical Coherent Tomography, and Confocal Laser Endomicroscopy

Endoscopically, urologists can suspect malignancy based solely on the presence of visible changes such as tumors or “red spots.” However, a multicenter study found that 37% of the biopsies performed on the basis of suspicious endoscopic findings resulted in a false-negative biopsy, emphasizing the subjectivity and attendant false-positive and false-negative rates of cystoscopy (Riedl et al., 2001). **The imperfect sensitivity of cystoscopy potentially explains, at least in part, the high rate of cancer recurrence soon after complete removal of all visible tumors.** It is likely that in many such cases, cancer was already present but not visible at the time of resection and simply became visible at follow-up when it became morphologically abnormal enough to differentiate from adjacent normal urothelium. To aid in identification of such tumors or satellite lesions, numerous techniques have been developed to enhance the use of standard cystoscopy.

Photoactive porphyrins accumulate preferentially in neoplastic tissue. Under blue light they emit red fluorescence, which can help in the diagnosis of indiscernible malignant lesions. Originally, studies conducted using intravesical application of 5-aminolevulinic acid (5-ALA), a precursor of photoactive porphyrin, resulted in residual systemic photosensitization (Lange et al., 1999). Hexaminolevulanic acid is a derivative that avoids the systemic photosensitization. Hexaminolevulanic acid has been approved widely for use in fluorescence or “blue light” cystoscopy, also known as photodynamic diagnosis, or PDD.

When blue light technology is used, small papillary tumors and almost one-third more cases of CIS overlooked on cystoscopy are identified (Fradet et al., 2007; Jichlinski et al., 2003; Schmidbauer et al., 2004) (Fig. 136.7). In one study, 96% of all tumors were detected with hexaminolevulinate (HAL) imaging compared with 77% with standard cystoscopy. Detection was improved for CIS (95% vs. 68%), and papillary tumors (96% vs. 85%) (Jocham et al., 2005). The clinical impact of improved tumor detection seems intuitive, and prospective evidence has shown that this decreases recurrence rates in patients who undergo HAL fluorescence cystoscopy compared with controls (Denzinger et al., 2007;

Filbeck et al., 2003; Grossman, 2007; Rink et al., 2013). The impact appears to persist for at least 4 years. There may be an impact on progression, although one study that examined this was underpowered to prove this trend (Stenzl et al., 2010). Fluorescence cystoscopy can also be used in the office setting with flexible cystoscopy (Fig. 136.8). Studies have demonstrated that even with flexible cystoscopy about 20% more recurrent papillary tumors and 34% more areas of CIS can be detected using fluorescence cystoscopy (Daneshmand et al., 2017). Another advantage of fluorescence cystoscopy is the ability to more accurately assess thoroughness of TUR. This would allow for more complete resection at the initial setting and reduce recurrence rates. A meta-analysis of all the studies incorporating this technique suggests that fluorescence cystoscopy can decrease recurrence up to 1 year and beyond, but not all studies consistently demonstrate this finding (Chou et al., 2017).

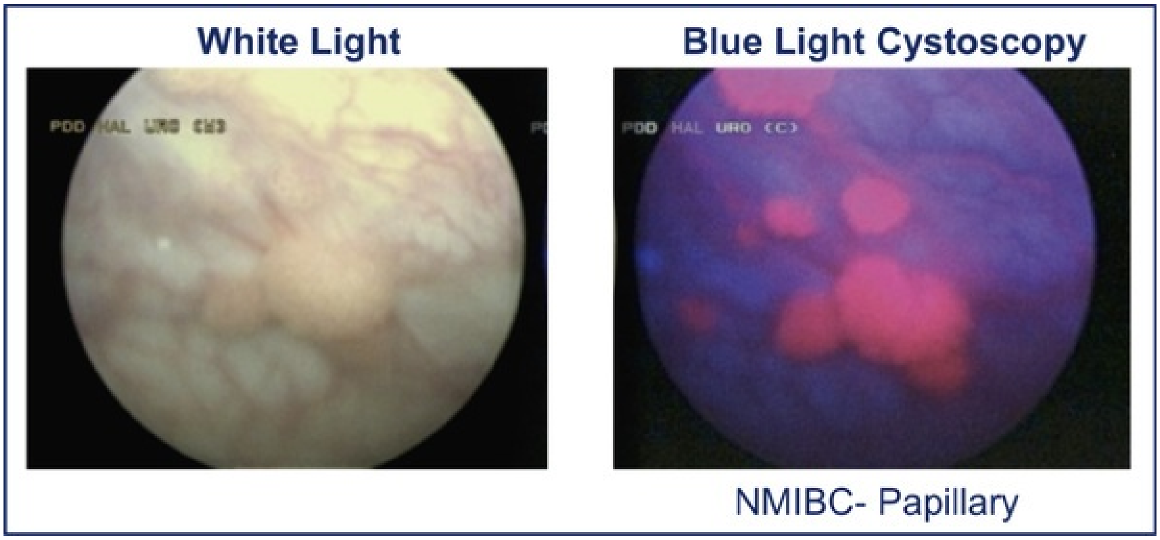

FIG. 136.7 White light cystoscopy reveals apparent normal-appearing mucosa juxtaposed with blue light cystoscopy demonstrating visual evidence of bladder cancer. Blue light cystoscopy reveals accumulation of hexaminolevulinate in the same area, ultimately found to contain non–muscle-invasive bladder cancer (NMIBC). (Image courtesy Dr. Siamak Daneshmand.)

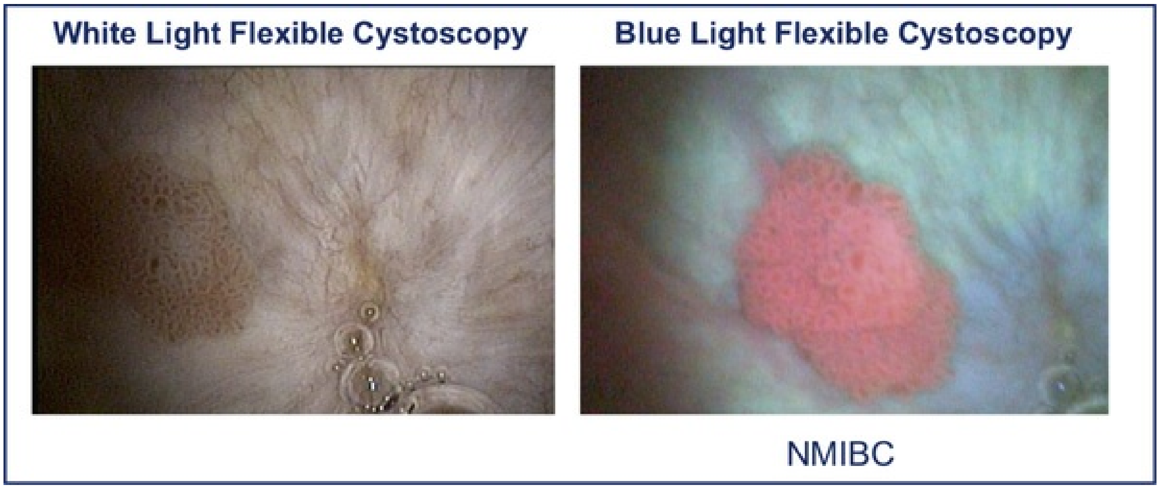

White Light Flexible Cystoscopy
Blue Light Flexible Cystoscopy
NMIBC

FIG. 136.8 White and blue light cystoscopy of non–muscle-invasive bladder cancer (NMIBC) using flexible cystoscopy after administration of hexaminolevulinate. (Image courtesy Dr. Siamak Daneshmand.)

Narrow band imaging (NBI) is an optical image enhancement technology intended to improve the visibility of blood vessels inherent to neoplastic processes. NBI light is composed of two specific wavelengths that are absorbed by hemoglobin; 415-nm light penetrates only the superficial mucosal layers, whereas 540-nm light penetrates more deeply. The combination allows improved visualization of tumors and enables distinguishing blood vessels on and below the surface from tumors. Several studies have been performed that reveal that NBI is able to detect more papillary tumors as well as CIS (Xiong et al., 2017). Initial studies suggest that about 13% more tumors could be diagnosed by NBI (Herr and Donat, 2008). More tumors were found using NBI compared with cystoscopy in 56% of cases. False-positive rates of NBI, however, are approximately 60%. TUR performed with NBI was also found to be more thorough, yielding reduced recurrence rates after TUR (Naselli et al., 2010, 2012). A more recent randomized trial conducted by Naito et al. (2016) demonstrated that the recurrence rates after TUR performed under white light cystoscopy and with NBI were no different. However, short-term recurrence rates at up to 3 months were reduced in low-risk tumors. This suggests that NBI-based resection may allow more thorough resection of surface tumors but cannot alter the pattern of recurrence in higher risk tumors.

Optical coherence tomography is a real-time imaging technology using near-infrared light (890–1300 nm) to provide cross-sectional images of biologic tissues. A small probe can be passed via cystoscope into bladder to allow real-time examination of bladder tumors. This technology is able to distinguish layers of urothelium and lamina propria as well as muscularis propria and distinguish between benign and malignant characteristics (Lerner and Goh, 2015). Early experience suggests more than 90% sensitivity, specificity, and negative predictive value with regard to detecting muscle invasion at time of cystoscopy (Lerner et al., 2008), which may facilitate determining appropriate depth of resection.

Confocal laser endomicroscopy involves administration of fluorescein and use of a 488-nm low-power laser to scan the tissue section of interest below the surface. Specific optical diagnostic criteria are then used to characterize tissue at the micro-architectural and cellular level to distinguish between normal urothelium, benign inflammatory lesions, and low- versus high-grade tumors (Chen et al., 2014).

Enhanced cystoscopic techniques are now included in the AUA guidelines (Chang et al., 2016) **as techniques to be considered for improving detection rates and for ensuring more complete TUR.**

Key Points: Endoscopic Surgical Management

- TURBT is performed to remove all visible tumors and to provide specimens for pathological examination to determine stage and grade.
- Repeat resection within 2 to 6 weeks is usually indicated in patients with high-grade disease, especially if no muscle was present in the initial TURBT.
- All suspicious lesions should be sampled, but random biopsies are not required in low-risk patients.
- Office-based fulguration and observation may be applied to certain low-risk patients.
- Fluorescence cystoscopy with 5-ALA derivatives and NBI improves the ability to visualize inconspicuous tumors and could reduce short- and long-term recurrence rates after TUR.

Intravesical Therapy

Perioperative Intravesical Therapy

It is believed that tumor cell implantation immediately after transurethral resection is responsible for many early recurrences, and this has been used to explain the observation that initial tumors are most commonly found on the floor and lower sidewalls of the bladder, whereas recurrences are often located near the dome as a result of "flotation" (Heney et al., 1981). Thus intravesical chemotherapy to kill such cells before implantation has been used for decades (Klan et al., 1991; Zincke et al., 1983).

Mitomycin C (MMC) appears to be the most effective adjuvant intravesical chemotherapeutic agent perioperatively, although epirubicin is used in Europe and direct comparative studies are lacking (Witjes and Hendricksen, 2008). **Consistent with its proposed mechanism of action to prevent tumor cell implantation, a single dose administered within 6 hours lessens recurrence rates, whereas a dose 24 hours later does not** (Duque and Loughlin, 2000; Isaka et al., 1992; Oosterlinck et al., 1993; Sekine et al., 1994; Solsona et al., 1999), and maintenance therapy does not reduce the risk further (Bouffioux et al., 1995; Tolley et al., 1996).

A meta-analysis of the use of perioperative chemotherapy found that low-risk patients experience a drop in the odds of recurrence from 48.4% to 36.7% at a median follow-up of 3.4 years. Patients with multiple tumors experienced a 56% reduction in the odds of recurrence. MMC, epirubicin, and pirarubicin significantly decreased the recurrence of single and multiple tumors. Thiotepa did not show the same benefit, but data were limited and some studies used diluted strengths (Sylvester et al., 2004). The number needed to treat (NNT) to prevent one recurrence in the meta-analysis was 8.5, so some authors have suggested that intravesical chemotherapy reduces overall cost of care by reducing the need for secondary resections. However, subsequent studies have shown that the tumors prevented are primarily smaller tumors that are often treated in the office or ambulatory surgery setting (Berrum-Svennung et al., 2008). In addition, the benefit appears limited to patients with low risk of recurrence (Gudjónsson et al., 2009), so the economic impact regarding recurrences remains controversial if recurrences are treated in any manner other than inpatient care (Lee et al., 2012; Rao and Jones, 2009). Randomized trial data have demonstrated that immediate intravesical instillation of mitomycin C reduces the risk of recurrence, even in patients treated with ongoing adjuvant instillations (Bosscheiter et al., 2018). **Hence, level 1 evidence demonstrates that a single-dose of mitomycin C or epirubicin instilled within 6 hours after resection reduces tumor recurrence, particularly for the initial presentation of a solitary papillary low-grade tumor.**

Studies using post-TUR instillation of gemcitabine have yielded mixed results. In one randomized study published by Böhle et al. (2009), recurrence-free survival at 1 year was no different in patients undergoing gemcitabine instillation vs saline. All patients in this study underwent more than 20-hour irrigation of the bladder with saline, thus raising the question of whether the continuous irrigation of the bladder post TUR can be helpful in reducing recurrence rates through mechanical extraction of floating cells. To this end, sterile water irrigation (Moskovitz et al., 1987) and normal saline continuous bladder irrigation have been evaluated and shown potential to reduce tumor recurrences after TURBT (Onishi et al., 2017). In a more recent phase III randomized trial completed by the Southwest Oncology Group (SWOG), intravesical administration of gemcitabine was again compared with saline in the immediate post-TURBT setting. In this trial, reported by Messing et al. (2017), gemcitabine demonstrated a 34% reduction in the likelihood of tumor recurrence with a very favorable side-effect profile. Hence gemcitabine remains an alternative option for perioperative intravesical chemotherapy.

The use of perioperative intravesical therapy is widespread in Europe but has achieved less frequent adoption in the United States (Madeb et al., 2009) potentially because of the cost, complexity, and potential for side effects, combined with the fact that it has not been shown to have adequate impact for recurrent, multiple, or high-grade tumors (Sylvester et al., 2004). A more detailed analysis of more than 2000 cases derived from 5 large practice sites in the United States revealed that post-TUR instillation of chemotherapy was used in an appropriate and judicious manner in up to 85% of cases and avoided mainly because of suspicion of perforation in many cases (Barocas et al., 2013).

Although local irritative symptoms are the most common complications of postoperative instillation, serious sequelae and rare deaths have also occurred, especially in patients with perforation during resection (Oddens et al., 2004). Other reported conditions associated with intravesical chemotherapy (with perioperative or multi-dose regimens) include chemical cystitis, cutaneous desquamation, decreased bladder capacity as a result of contractures, calcified eschars, and complications or added difficulty of subsequent cystectomy (Fig. 136.9; Cliff et al., 2000; Doherty et al., 1999; Nieuwenhuijzen et al., 2003; Oddens et al., 2004; Shapiro et al., 2006). **Chemotherapy should be withheld in patients with extensive resection or when there is concern about perforation.**

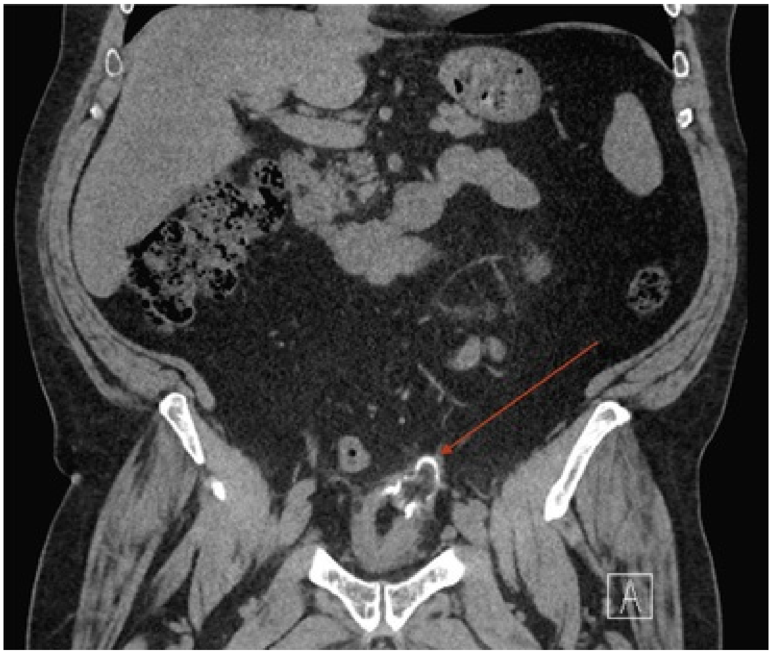

FIG. 136.9 CT image taken from image of a 59-year-old male who received perioperative administration of mitomycin C at time of transurethral resection of bladder tumor in the setting of extravesical perforation. This patient subsequently developed calcified, necrotic tissue associated with non-healing bladder ulcer (as pictured in image with *red arrow* pointing to calcified region) and ultimately required radical cystectomy with ileal neobladder secondary to refractory symptoms.

BCG can never be safely administered immediately after TUR because the risk of bacterial sepsis and death is high.

Key Points: Perioperative Intravesical Therapy to Prevent Tumor Implantation

- Single-dose intravesical chemotherapy administered within 6 hours of resection reduces recurrence of low-risk tumors with significant impact in the setting of initial presentation of solitary low-grade papillary tumors.

- The incremental benefit in patients with recurrent or multiple tumors is limited.
- No benefit has been found in patients with high-grade disease.

Intravesical Immunotherapy

Bacille Calmette-Guérin

BCG is an attenuated mycobacterium developed as a vaccine for tuberculosis that has demonstrated antitumor activity in several different cancers including UC (Morales et al., 1976). The original regimen described by Morales included a percutaneous dose, which was discontinued after success with a similar intravesical regimen by Brosman (1982).

BCG powdered vaccine is reconstituted with 50 mL of saline and is routinely administered through a urethral catheter. **Treatments are typically started 2 to 4 weeks after tumor resection, allowing time for re-epithelialization of the bladder after TURBT, thereby minimizing the potential for intravasation of live bacteria** (Lamm et al., 1992)**. A urinalysis is usually performed immediately before instillation to further confirm absence of infection or significant bleeding to decrease the likelihood of systemic uptake of BCG. In the event of a traumatic catheterization, the treatment should be delayed for at least several days,** depending on the extent of injury. Active urinary tract infection is often considered an indication to delay treatment until it has been managed; however, recent publications question the need to avoid BCG in the presence of asymptomatic bacteriuria (Herr, 2012). **After instillation, the patient should retain the solution for at least 1 to 2 hours.** Some clinicians have advocated that the patient turn from side to side to bathe the entire urothelium, but there is no scientific support for this practice. Fluid, diuretic, and caffeine restriction before instillation limits dilution of the agent by urine and facilitates adequate retention of the agent for 2 hours (Lamm et al., 2000b). Patients are commonly instructed to clean the toilet with bleach, although there is no demonstrable risk of close contact infection.

Mechanism of Action

Intravesical immunotherapy results in a robust local immune response characterized by induced expression of cytokines in the urine and bladder wall and by an influx of granulocytes and mononuclear and dendritic cells (Shen et al., 2008). **The initial step appears to be direct binding to fibronectin within the bladder wall,** subsequently leading to direct stimulation of cell-based immunologic response and an antiangiogenic state. Numerous cytokines involved in the initiation or maintenance of inflammatory processes including tumor necrosis factor-α (TNF-α), granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon-γ (IFN-γ), and interleukin-1 (IL-1), IL-2, IL-5, IL-6, IL-8, IL-10, IL-12, and IL-18 have been detected in the urine of patients treated with intravesical BCG and other immunostimulatory agents. Release of tumor necrosis factor–related apoptosis inducing ligand (TRAIL) also appears to be a key event in propagation of the BCG response and is associated with response to BCG (Ludwig et al., 2004). **The observed pattern of cytokine induction with preferential upregulation of IFN-γ, IL-2, and IL-12 reflects induction of a T-helper type-1 (Th1) response.** This immunologic response activates cell-mediated cytotoxic mechanisms believed to underlie the efficacy of BCG and other agents in the prevention of recurrence and progression (Bohle and Brandau, 2003). BCG may concomitantly stimulate IL-10, resulting in the suppressive Th2 response. Overall, response to intravesical immunotherapy may be limited if a patient has an immunosuppressive disease or by advanced age (Joudi et al., 2006a, 2006b). More recent data, however, suggest that BCG can be used safely in patients who are immunosuppressed such as transplant recipients and those on systemic steroid therapy without significant increase in side effects or BCG sepsis (Herr and Dalbagni, 2013). Response to BCG therapy may not be as robust as seen in patients who are not similarly immunosuppressed.

Bacille Calmette-Guérin Treatment of Carcinoma in Situ

BCG is the most commonly used intravesical agent in the United States, whereas intravesical chemotherapy is more commonly used in other parts of the world. BCG is approved for intravesical treatment of NMIBC by the US Food and Drug Administration (FDA). Before the adoption of BCG intravesical therapy, CIS reportedly progressed at an average rate of 7% per year (Zincke et al., 1985). **The initial tumor-free response rate is as high as 84%** (Brosman, 1982; De Jager et al., 1991; Hudson and Herr, 1995; Lamm et al., 2000a, 2000b, 2000c). **Approximately 50% of patients experience a durable response for a median period of 4 years. Over a 10-year period, approximately 30% of patients remain free of tumor progression or recurrence, so close follow-up is**

mandatory. The majority of these occur within the first 5 years (Herr et al., 1992). Herr et al. (1989) **reported progression in 19% of initial responders at 5 years but found the rate to be 95% in nonresponders—findings confirmed by other investigators** (Coplen et al., 1990; Harland et al., 1992). **The current AUA guidelines panel recommends BCG as the preferred initial treatment option for high-risk bladder tumors and as a potential option either up front or preferably after intravesical chemotherapy for intermediate-risk tumors** (Chang et al., 2016).

BCG has gained a preeminent role in North America on the basis of higher efficacy reports compared with intravesical chemotherapy (O'Donnell, 2007). BCG is more effective than intravesical mitomycin C but only when comparing BCG induction + maintenance doses versus a 6-week induction course of mitomycin alone. Furthermore, intravesical BCG instillation is associated with reduced risk for recurrence as well as progression (Chou et al., 2017), whereas intravesical chemotherapy does not appear to affect progression. BCG instillation is, however, associated with a greater risk of adverse events including cystitis, dysuria, hematuria, and fever as compared with other intravesical therapies (Chou et al., 2017). In more than 600 patients, there was a 68% complete response rate to BCG and a 49% complete response rate to chemotherapy. In responders, 68% of patients treated with BCG remained free of disease as compared with 47% of patients receiving chemotherapy, on the basis of a median follow-up of 3.75 years. The overall disease-free rates were 51% and 27%, respectively (Sylvester et al., 2005). More recently, meta-analysis data have further identified that mitomycin C, doxorubicin, epirubicin, and thiotepa are associated with a decreased risk of recurrence. Unlike BCG, however, these intravesical chemotherapeutic agents do not appear to decrease the risk of progression (Chou et al., 2017).

Bacille Calmette-Guérin Treatment of Residual Tumor

Intravesical BCG can effectively treat residual papillary lesions but should not be used as a substitute for surgical resection. Investigators have demonstrated a nearly 60% response by residual tumor with intravesical BCG alone (Brosman, 1982; Coplen et al., 1990; Schellhammer et al., 1986).

Carcinoma of the mucosa or the superficial ducts of the prostate can be adequately treated by BCG with a 50% tumor-free rate. A limited TURP or fulguration can be effective in decreasing tumor burden and facilitating exposure of the prostate surface to BCG administration (Bretton et al., 1990;

Schellhammer et al., 1995).

Bacille Calmette-Guérin Prophylaxis to Prevent Recurrence

Early single-center studies demonstrated an advantage in decreased tumor recurrence of approximately 30% when a 6-week course of BCG was administered after recovery from TURBT (Brosman, 1982; Morales et al., 1992). In several larger series, tumor recurrence after TURBT was reduced by 20% to 65%, for an average of approximately 40% (Herr et al., 1992; Krege et al., 1996; Melekos et al., 1993; Pagano et al., 1991a, 1991b). A meta-analysis of 2000 patients with Ta, T1, and/or CIS disease found that patients receiving maintenance BCG had a statistically decreased rate of recurrence compared with those receiving induction therapy alone (Han and Pan, 2006). A subsequent reevaluation of the published data concluded that 3 years of maintenance therapy was supported by the literature but that patients with intermediate-risk disease may be equally managed with 1 year of maintenance (Ehdaie et al., 2013). A more recent meta-analysis further identifies a decreased risk of recurrence with BCG administration (Chou et al., 2017).

The efficacy of BCG after TURBT for high-risk papillary disease has been demonstrated in several series of T1 lesions, with recurrence rates of 16% to 40% and progression rates of 4.4% to 40%, a substantial improvement compared with TUR alone (Cookson and Sarosdy, 1992; Gohji et al., 1999; Herr, 1997; Hurle et al., 1999a, 1999b; Jimenez-Cruz et al., 1997; Pansadoro et al., 1995). Tumor multiplicity and associated CIS were associated with increased risk of progression. Substaging lesions on the basis of the presence or absence of muscularis mucosae invasion in a series of 49 patients did not improve prediction of recurrence (69% vs. 65%) or progression (22% vs. 29%) after BCG therapy (Kondylis et al., 2000).

Impact of Bacille Calmette-Guérin on Progression

Although reports of the impact of BCG on tumor recurrence are compelling, the greater need is the potential for impact on progression. In 403 patients with CIS, BCG reduced the risk of progression by 35% compared with intravesical chemotherapy (Sylvester et al., 2002).

In a randomized trial of 86 patients with high-risk superficial disease, Herr et al. (1988) demonstrated a greater delay in interval progression for BCG patients versus TUR controls. In addition, the cystectomy rate was significantly decreased for CIS patients treated with BCG (11% vs. 55% for controls), and time-to-cystectomy was delayed in the BCG group. However, only 27% of patients were alive with an intact functioning bladder after follow-up over 10 to 15 years, so this apparent advantage is temporary in many cases (Cookson et al., 1997). Available data suggest that BCG can delay progression of high-risk bladder cancer, yet the long-term survival advantage is not fully defined.

Nevertheless, meta-analyses have concluded that BCG reduces the risk of progression. Progression at 2.5 years' median follow-up was reduced by 27% (9.8% for BCG vs. 13.8% for non-BCG) in one (Sylvester et al., 2002) and by 23% (7.7% for BCG vs. 9.4% for MMC) at 26-month median follow-up in another analysis (Bohle and Bock, 2004). More recent meta-analysis data further identify reduced risk of progression in patients treated with BCG with an RR of 0.39 based on data from 4 trials (Chou et al., 2017). In each meta-analysis the **superior results with BCG were concentrated in trials using BCG maintenance therapy. In contrast, no chemotherapy trials have achieved a significant reduction in progression** (Chou et al., 2017; Grossman et al., 2008).

Determining Optimum Bacille Calmette-Guérin Treatment Schedule

The optimal treatment schedule and dose for BCG have not been established (Herr et al., 2011). In reality, **several studies and AUA guidelines suggest that a 6-week induction course alone is insufficient to obtain an optimal response in many patients and that maintenance therapy is requisite** (Chang et al., 2016; Lamm et al., 2000a,b,c; Palou et al., 2001).

The average additional response to a second induction course is 25% in those patients treated for prophylaxis and 30% in CIS patients (Bohle and Bock, 2004; Bretton et al., 1990; Coplen et al., 1990; Haaff et al., 1986; Kavoussi et al., 1988; Sylvester et al., 2002). However, **additional courses of BCG to treat refractory patients after a second 6-week course are accompanied by a significant risk of tumor progression in 20% to 50% of patients** (Nadler et al., 1994). Catalona et al. (1987) reported roughly a 7% actuarial risk of progression with every additional course of BCG therapy. **Response to BCG at 6 months can be used as a predictor of prognosis, with the number of patients developing progressive disease being significantly higher among nonresponders** (Orsola et al., 1998).

The **Southwest Oncology Group (SWOG)** reported the most significant impact of maintenance therapy. Patients received a **6-week induction course**

followed by 3 weekly instillations at 3 and 6 months and every 6 months thereafter for 3 years. Estimated median recurrence-free survival was 76.8 months in the maintenance arm and 35.7 months in the control arm (*P* = 0.0001). Average recurrence-free survival was 111.5 months in the control arm and could not be estimated in the maintenance arm (*P* = 0.04). Overall 5-year survival was 78% in the control arm and 83% in the maintenance arm. No toxicities above grade 3 were observed, yet **only 16% of patients tolerated the full dose-schedule regimen.** Two-thirds of the patients who stopped BCG because of side effects did so in the first 6 months, suggesting that the side effects do not increase appreciably with additional time on therapy. **Because of the fact that the treatment group fared better despite most patients having failed to complete the full course of therapy, the maximum benefit may have been achieved earlier. Shorter maintenance schedules and reduced dosages may accomplish the same results with less toxicity** (Lamm et al., 2000a).

More recent data from a randomized non-inferiority study published by Oddens et al. (2013) clarify the use of different durations of maintenance therapy based on risk stratification of the tumor. For patients with intermediate-risk disease, a 1-year course of maintenance BCG was administered at months 3, 6, and 12. In patients with high-risk disease, the instillations were continued every 6 months thereafter up to 3 years. Full dose and one-third dose of BCG were tested in this four-arm trial. The results demonstrated that patients with intermediate-risk disease benefited from 1 year of maintenance therapy with full-dose BCG, whereas patients with high-risk disease obtained the most benefit with 3 years of full-dose BCG therapy. Only 7.1% and 8.3% of patients who received 1 year of maintenance and 3 years of maintenance, respectively, had to discontinue treatment because of side effects. For high-grade T1 lesions or CIS, maintenance therapy has proven superior in multiple studies (Palou et al., 2001). **The determination of whether the optimal treatment schedule should be as described in the SWOG study, monthly, or on some other schedule remains undefined, and optimal duration of a monthly maintenance schedule, if chosen, is not definitively established. However, based on the trial reported by Oddens et al., it appears that the SWOG regimen yields the best results reported to date** (Lamm et al., 2000a, 2000b, 2000c; O'Donnell, 2005, Oddens et al., 2013).

Several investigators have evaluated the potential for BCG dose reduction (Martinez-Pineiro et al., 1995; Melekos et al., 1993; Morales et al., 1992; Pagano et al., 1995). In general, a decrease in toxicity with no statistical difference in efficacy has been noted in small series (Hurle et al., 1996; Mack and Frick, 1995; Pagano et al., 1991b), although multifocal and high-grade tumors may respond better to full dosage (Martinez-Pineiro et al., 2002). Recent meta-analysis data have not demonstrated clear differences between standard and lower doses of BCG in recurrence, progression, or risk of mortality (Chou et al., 2017). Some studies have shown an upregulation of the Th1 response with a lower dose of BCG. Lengthening of the instillation interval may decrease side effects without loss of efficacy (Bassi et al., 2000). Studies in Europe, where BCG inoculation for tuberculosis is more common than in North America, suggest that the dose may be safely reduced by half (Martinez-Pineiro et al., 2002). The difference in response to doing so in immunologically naive North Americans is unknown, but Morales et al. (1992) found a significant decrease in response rates (67% vs. 37%), especially for patients with CIS in combination with papillary tumors treated with the reduced dose. The results from the EORTC trial reported by Oddens et al. (2013), wherein worse responses were observed with one-third dose BCG raises questions about the difference in efficacy between the full-dose and reduced-dose BCG. **Given the variability of this data, the most recent AUA guidelines suggest there is insufficient evidence to prescribe a particular strength of BCG** (Chang et al., 2016).

Antibiotic therapy may have a beneficial effect in treating or preventing systemic side effects of BCG therapy, yet it may also inhibit the effectiveness of BCG therapy if it is given routinely for urinary tract prophylaxis during a course of BCG therapy (Durek et al., 1999a, 1999b). Quinolones were previously thought to affect the viability of BCG (Durek et al., 1999b; Boxes 136.1 and 136.2). However, subsequent randomized studies have demonstrated that short-term use of a quinolone antibiotic such as ofloxacin or prulifloxacin for 24 to 48 hour post-BCG can reduce the cystitis-related side effects of BCG instillation in up to 20% of patients with the most significant reduction in side effects grade II or higher seen in patients after the fourth instillation (Colombel et al., 2006; Damiano et al., 2009). Post-instillation use of quinolones also reduced treatment delays and discontinuations while not affecting recurrence or progression rates. Many urologists use this routinely as part of BCG instillation protocol. A single dose of isoniazid (INH) or a 24-hour duration of INH has been used before or around the time of BCG instillation to reduce side effects. The results of this approach have been mixed with one study demonstrating a reduction and another study showing no change (Al Khalifa et al., 2000; van der Meijden et al., 2001).

Box 136.1

Contraindications to Bacille Calmette-Guérin (BCG) Therapy

Absolute Contraindications

Immunosuppressed and immunocompromised patients[a]
Immediately after transurethral resection on the basis of the risk of intravasation and septic death
Personal history of BCG sepsis
Gross hematuria (intravasation risk)
Traumatic catheterization (intravasation risk)
Total incontinence (patient will not retain agent)

Relative Contraindications

Urinary tract infection (intravasation risk)
Liver disease (precludes treatment with isoniazid if sepsis occurs)
Personal history of tuberculosis (risk theorized but unknown)
Poor overall performance status
Advanced age

No or Insufficient Data on Potential Contraindications

Patients with prosthetic materials have not been shown to have increased risk of infectious or other complications in limited literature (Rosevear et al., 2010)
Ureteral reflux
Anti–tumor necrosis factor medications (theoretically predispose to BCG sepsis)

---

[a] Recent small series suggest this may not be an absolute contraindication (Herr, 2012).

From Ehlers S: Why does tumor necrosis factor targeted therapy reactivate tuberculosis? *J Rheumatol (Suppl)* 74:35–39, 2005.

Box 136.2

Management of Bacille Calmette-Guérin (BCG) Toxicity

Grade 1: Moderate Symptoms <48 Hours

Mild or moderate irritative voiding symptoms, mild hematuria, fever <38.5°C

Assessment

Possible urine culture to rule out bacterial urinary tract infection

Symptom Management

Anticholinergics, topical antispasmodics (phenazopyridine), analgesics, nonsteroidal anti-inflammatory drugs

(Asymptomatic prostatic granulomas that occur after BCG therapy can occasionally mimic prostate cancer clinically and/or radiographically. There is no evidence to support treatment in this setting [Suzuki et al., 2013].)

Grade 2: Severe Symptoms and/or >48 Hours

Severe irritative voiding symptoms, hematuria, or symptoms lasting >48 h

All maneuvers for grade 1, plus the following:

Assessment

Urine culture, chest radiograph, liver function tests

Management

Consider dose reduction to one-half to one-third of dose when instillations resume.
Treat culture results as appropriate.
Can also consider pre-treating with a single dose of isoniazid before each subsequent instillation

Antimicrobial Agents

Administer isoniazid and rifampin orally until symptom resolution.
Also use vitamin B6 or pyridoxine.
Do not use monotherapy.
Observe for rifampin drug-drug interactions (e.g., warfarin).
Monitor liver function tests.

Grade 3: Serious Complications (Hemodynamic Changes, Persistent High-Grade Fever)

Allergic Reactions (Joint Pain, Rash)

Perform all maneuvers described for grades 1 and 2, plus the following:
Isoniazid and rifampin, depending on response.
Also use vitamin B6 or pyridoxine.

Solid Organ Involvement (Liver, Lung, Kidney)

Stop BCG instillations. Initiate antimycobacterial therapy with isoniazid, rifampin. If symptoms persist, consult with Infectious Disease specialist with expertise in anti-tuberculous therapy. Can add ethambutol.
Cycloserine often causes severe psychiatric symptoms and is to be strongly discouraged.
BCG is almost uniformly resistant to pyrazinamide, so this drug has no role.
Consider prednisone when response is inadequate or for septic shock (never given without effective antibacterial therapy).

Assessing the response to BCG is a critical component to successful treatment with this agent. It is largely understood that the patient's immune response is a critical predictor for outcomes with BCG. As such, Kamat et al. (2016) have developed a nomogram to predict response to BCG based on a cytokine panel. This cytokine panel for response to intravesical therapy (CyPRIT) evaluates a number of urinary cytokines after BCG administration, with a nomogram based on these findings demonstrating prediction of recurrence with AUC of 86%. This and similar techniques have the potential to provide a useful tool for predicting response to immunotherapy.

Interferon

IFNs are glycoproteins produced in response to antigenic stimuli. These agents have multiple antitumor activities including inhibition of nucleotide synthesis; upregulation of tumor antigens, antiangiogenic properties; and stimulation of cytokine release with enhanced T- and B-cell activation, as well as enhanced natural killer cell activity (Naitoh et al., 1999). Among several subtypes, IFN-α has been the most extensively studied. It is most active in doses of at least 100 million units, although optimal dose and administration schedule have yet to be determined (Belldegrun et al., 1998; Torti et al., 1988).

IFN as a solitary agent is more expensive and less effective than BCG or intravesical chemotherapy in eradicating residual disease, preventing recurrence of papillary disease, and treating CIS (20% to 43% complete response). Its long-term efficacy for CIS is less than 15% (Belldegrun et al., 1998). A randomized trial demonstrated CIS responses from 5% at low doses (10 million units) to as high as 43% at high doses (100 million units) (Torti et al., 1988). As a prophylactic agent, IFN alone demonstrated recurrence rates that were inferior in general to those of BCG alone (from 60% to 16%) (Glashan, 1990; Kalble et al., 1994). It has demonstrated limited activity against T1 tumors (Malmstrom, 2001). However, it can occasionally be effective in patients in whom BCG has failed (15% to 20% complete response; see later).

IFN-α has also been studied in a combination treatment regimen with either chemotherapy or BCG (Bercovich et al., 1995; Stricker et al., 1996). There appeared to be additive effects with either epirubicin or MMC. **Several trials investigated the combination of BCG and IFN and suggested the potential superiority of the combination or the possibility of decreasing the dose of BCG, which may reduce side effects. Initial work by O'Donnell et al.** (1999) **reported a 63% disease-free rate at 12 months and 53% at 24 months with use of combination therapy.** A subsequent randomized trial conducted in BCG-naive patients compared BCG with BCG + interferon α-2b in a cohort of 670 patients (Nepple et al., 2010). Patients were also secondarily randomized to receiving megadose multivitamins or recommended daily allowance of multivitamins. There appeared to be no difference among all four groups, suggesting that the addition of interferon α-2b as well as megadose multivitamins did not significantly affect response to BCG. At this point the main benefit of adding interferon α-2b to BCG appears to be the fact that the dose of BCG can be reduced to a third or lower without compromising the efficacy of the regimen.

Investigational Immunotherapeutic Agents

A number of novel agents have shown potential, but none has reached clinical practice. Keyhole limpet hemocyanin (KLH) from the hemolymph of the mollusk *Megathura crenulata* is a nonspecific immune stimulant whose potential effectiveness in UC was identified serendipitously (Jurincic et al., 1989; Olsson et al., 1974). Recent work suggests continued promise for this agent but no clear superiority to available agents (Lammers et al., 2012). Mycobacterial cell wall DNA extract contains a mixture of immunostimulatory DNA attached to antigenic cell wall. Phase II trial results indicate success rates less than those achieved with BCG but with good tolerability; however, no agent is commercially available (Morales et al., 2001, 2009). A phase II single-arm study of this agent was conducted in 129 patients by Morales et al. (2015), which demonstrated an overall disease-free survival rate of 19% at 2 years. The disease-free survival was higher (35%) in patients with papillary-only tumors. A phase III study of the same agent was suspended because of poor accrual. Only 75 patients of an anticipated 450 patients were enrolled, and no significant difference between groups was noted.

IL-2 is highly expressed after BCG stimulation and is a key component of the Th1 immune response. Preclinical data suggest a potential benefit and little toxicity (Horinaga et al., 2005). Multiple studies have documented the potential use of either intravesical IL-2 alone, with BCG, or with BCG and IFN (Shapiro et al., 2007). Preclinical data identifying the efficacy of liposome-mediated intravesical IL-2 with biologic response modifiers have elucidated long-term T-cell memory against muscle-invasive bladder cancer and NMIBC (Horiguchi et al., 2000; Larchian et al., 2000). Combination therapy with BCG and intravesical interferon α-2b and IL-2 along with granulocyte colony-stimulating factor has been shown to yield surprisingly high response rates in patients who had previously failed intravesical BCG therapy (Steinberg et al., 2017).

Key Points: Immunotherapy

- Intravesical BCG has higher efficacy and side effects compared with intravesical chemotherapy.
- BCG should be used cautiously for patients with low-risk disease because of concern about side effects.
- Management of infectious complications of BCG is shown in Box 136.2.
- BCG is the only agent shown to delay or reduce high-grade tumor progression.
- The optimal dose and the treatment schedule for BCG are undetermined, but results are better with maintenance therapy, if tolerated.
- BCG is contraindicated in the setting of a disrupted urothelium because of the risk of intravasation and BCG sepsis.

Intravesical Chemotherapy

Induction therapy using chemotherapeutic agents instilled within 6 hours of TURBT has demonstrated a clear impact on recurrence rates, as described earlier and are recommended in current clinical guidelines (Chang et al., 2016). However, the role of chemotherapy in the adjuvant setting is less clear compared with the efficacy of BCG. A **SWOG trial that compared doxorubicin and BCG showed a 15% progression rate in patients receiving BCG compared with a 37% progression rate in patients receiving chemotherapy** (Lamm et al., 1991). In addition, data have suggested that BCG with maintenance confers a lower risk of recurrence compared with mitomycin C, doxorubicin, epirubicin, and thiotepa (Chou et al., 2017). Nevertheless, the risk of BCG infectious complications is nonexistent with chemotherapy, leading many urologists to continue using these agents. The main side effects of most chemotherapeutic agents appear to be local such as cystitis and dermatitis if the agent comes in contact with skin. On rare occasions systemic absorption can occur through the skin or bladder, resulting in hematopoietic side effects or nausea.

The agents are summarized in Table 136.4.

TABLE 136.4

Comparisons Among Intravesical Agents

AGENT	PERIOPERATIVE USE	RISK GROUP	CYSTITIS (%)	OTHER TOXICITY	DRO (%)
Doxorubicin (Adriamycin)	Yes	Low to intermediate	20–40	Fever, allergy, contracted bladder, 5%	2–16
Epirubicin	Yes	Low to intermediate	10–30	Contracted bladder rare	3–6
Thiotepa	Yes	Low to intermediate	10–30	Myelosuppression 8%–19%	2–11
Mitomycin	Yes	Low to intermediate	30–40	Rash 8%–19%, contracted bladder 5%	2–14
BCG	No	Intermediate to high	60–80	Serious infection, 5%	5–10
Interferon	No	Salvage	<5	Flulike symptoms 20%	Rare
Gemcitabine	Yes	Salvage	Mild	Occasional nausea	<10
Valrubicin	No	Salvage	Mild	UTI, abdominal pain, asthenia	<10

BCG, Bacille Calmette-Guérin; *UTI,* urinary tract infection.

Modified from O'Donnell MA: Practical applications of intravesical chemotherapy and immunotherapy in high-risk patients with superficial bladder cancer. *Urol Clin North Am* 32:121–131, 2005.

Thiotepa

Thiotepa (triethylenethiophosphoramide) is the only chemotherapeutic agent approved by the FDA specifically for the intravesical treatment of papillary bladder cancer. It is an alkylating agent and is not cell cycle specific. In controlled clinical trials ($n = 950$ patients), it has been shown to significantly decrease tumor recurrence in 6 of 11 studies by up to 41% (mean decrease, 16%). Systemic side effects can be seen because of its low molecular weight, resulting in up to half of administered doses being absorbed, risking hematopoietic toxicity (Thrasher and Crawford, 1992). As such, most centers have substituted its use with BCG or one of the aforementioned chemotherapeutic agents.

Doxorubicin

Doxorubicin (Adriamycin) is anthracycline antibiotic that acts by binding DNA base pairs, inhibiting topoisomerase II, and inhibiting protein synthesis. In a review, **doxorubicin demonstrated a 13% to 17% improvement over TUR in preventing recurrence but no advantage in preventing tumor progression (15.2% vs. 12.6%)** (Kurth et al., 1997). The principal side effect of intravesical doxorubicin is chemical cystitis, which can occur in up to half of the patients. Reduced bladder capacity has been reported in several series (Thrasher and Crawford, 1992).

The **doxorubicin derivative epirubicin decreases recurrence compared with TUR alone by 12% to 15%** (Oosterlinck et al., 1993). This was demonstrated with a single, immediate, perioperative dose, as well as in full 8-week courses of intravesical therapy. Epirubicin is available for use in patients with UC in Europe and is FDA approved but is unavailable for treatment of UC in the United States. At least one study conducted in Japan combined epirubicin with lactobacillus casei, a probiotic agent commonly used in Japan (Naito et al., 2008). Recurrence rates were reduced by 15% in patients using lactobacillus casei as an oral supplement during epirubicin instillation therapy.

Valrubicin

Valrubicin is a semisynthetic analogue of doxorubicin that was approved by the FDA for treatment of BCG-refractory CIS in patients who cannot tolerate cystectomy; the drug became available in 2009 in the United States (Greenberg et al., 1997; Grossman et al., 2008; Sweatman et al., 1991). In a cohort of 90 patients with BCG-refractory CIS, only 21% demonstrated a complete response (Steinberg et al., 2000), so its use is not widespread.

Mitomycin C

MMC is an alkylating agent that inhibits DNA synthesis. The drug is usually instilled weekly for 6 to 8 weeks at dose ranges from 20 to 60 mg. A meta-analysis of nine clinical trials compared its effect on disease progression with that of BCG. With a median follow-up of 26 months, **7.67% of the patients in the BCG group and 9.44% of the patients in the MMC group developed tumor progression** (Bohle and Bock, 2004). More recently, Chou et al. (2017), in a meta-analysis comparing MMC with BCG, identified no differences between BCG and MMC with regard to recurrence risk; however, BCG fared better in the subgroup of trials using maintenance (RR 0.79). MMC was also found to have higher risk of progression than BCG in this same study. **Another review found a 38% reduction in tumor recurrence with MMC. This was not as effective as BCG but was considered in most studies to make MMC a viable option for reduction in recurrence (but not for progression) in light of its lesser side effects** (Huncharek et al., 2001).

Optimization of MMC delivery can result in halving of the recurrence rate in some studies. This can be achieved by eliminating residual urine volume, fasting overnight, using sodium bicarbonate to reduce drug degradation, and increasing concentration to 40 mg in 20 mL (Au et al., 2001). The use of local microwave therapy in conjunction with MMC, 20 mg/50 mL, reduced recurrence rates from 57.5% to 17.1% in a multicenter trial. A study using microwave therapy with higher doses of 40 to 80 mg for 6 to 8 weeks in high-grade bladder cancer found a recurrence-free rate of 75% at 2 years (Gofrit et al., 2004; van der Heijden et al., 2004).

Electromotive intravesical MMC appears to improve drug delivery into bladder tissue by four- to sevenfold (Di Stasi and Riedl, 2009; DiStasi et al., 1999). The electromotive current is usually delivered as a pulsed current of 40 to 60 mA/sec to a maximum of 20 mA over 30 minutes through two cathode electrodes placed over the gel-smeared skin of the lower abdominal wall. With this treatment was reported reduction in recurrence rates with MMC from 58% to 31%, whereas patients in the BCG control arm had a 64% recurrence rate (Di Stasi et al., 2003). A randomized trial conducted in patients with primary and recurrent T1 urothelial carcinoma comparing BCG alone with a combination of BCG alternating with electromotive MMC reported lower recurrence and progression rates with the combination treatment as well as better overall and cancer-specific survival (Di Stasi et al., 2006). Peak plasma MMC was significantly higher in the electromotive group, supporting its presumed mechanism of action.

More recent approaches have used the approach of heating the bladder along with mitomycin instillation to incite a mild inflammation of the bladder wall, which potentiates the action of mitomycin but can also improve the effectiveness of BCG (DiStasi et al., 2011). The interior of the bladder can be heated to a temperature of about 42°C using radiofrequency needles emerging from the tip of a urethral catheter. The device is called the Synergo-RITE (Medical Enterprises Group, Amstelveen, The Netherlands). The intravesical heating enhances the absorption and activity of mitomycin C similar to when the electric current is delivered transabdominally. Several single arm studies have demonstrated encouraging results. Randomized studies comparing chemohyperthemia (as it is termed) to plain mitomycin instillation have demonstrated up to a threefold lower recurrence rate with electromotive mitomycin or chemohyperthermia (Colombo et al., 2011). However, a subsequent randomized study by Arends et al. (2016), which compared electromotive mitomycin to BCG instillation, demonstrated lower 2-year recurrence-free survival in those receiving electromotive mitomycin, although this difference was not statistically significant. There was an observed higher toxicity in those receiving the electromotive MMC. Gan et al. (2016) have also published work involving a combination protocol of BCG in conjunction with electromotive MMC demonstrating promising results of 87% initial complete response with 73% of their initial first responders remaining disease free at 2 years.

An alternative method of delivering heated mitomycin C into the bladder termed hyperthermic intravesical chemotherapy (HIVEC) can be delivered using the Bladder Recirculation System (BRC) developed by Combat Medical (Hertfordshire, United Kingdom). This method involves instilling a solution of mitomycin that is heated to 42°C into the bladder in the form of a continuously recirculating irrigation. Patients have been treated in a neoadjuvant fashion before TUR and in an adjuvant fashion after TUR (Sousa et al., 2016). Surprisingly, 62% of patients who received the treatment before TUR had chemoablation of their tumors and a negative biopsy at TUR. Of those who received the treatment in an adjuvant fashion, 2-year risk of recurrence was 12%. All treatments were focused on patients with intermediate-risk disease. Although these results are exciting, more data from randomized trials are needed before this approach can be incorporated into the current treatment paradigm (Jung et al., 2017).

Other Intravesical Therapeutic Agents

Gemcitabine and the taxanes **paclitaxel** and **docetaxel** have demonstrated activity against metastatic bladder cancer (Calabro and Sternberg, 2002). Intravesical gemcitabine can be safely administered either weekly or twice weekly for six to eight treatments. Minimal systemic absorption occurs through the bladder. Early small phase I and phase II studies demonstrated reduction of recurrence of 39% to 70%, including modest efficacy in heavily pretreated BCG-refractory patients (Maymi et al., 2004; O'Donnell, 2005). Di Lorenzo et al. (2010) completed a randomized phase II trial using intravesical gemcitabine versus re-induction course of BCG in patients who failed one course of BCG and identified improved 2-year disease-free survival but no significant difference in risk of progression or cystectomy rates. An additional SWOG phase II trial evaluated gemcitabine after two failed courses of intravesical BCG and identified a 2-year disease-free survival rate of 21% (Skinner et al., 2013). As such, gemcitabine appears to have a role, particularly in the setting of previous BCG failure.

Taxanes have also been formulated into an active intravesical treatment (Lu et al., 2004). Robins et al. (2017) have published a phase II trial using nanoparticle albumin-bound paclitaxel in patients with disease recurrence after BCG. This trial identified a complete response rate of 36% and recurrence-free survival rate of 18% with a median follow-up of 41 months. Although data remain limited, these and other agents remain under investigation for patients with BCG failure.

Apaziquone or EOquin is an indoloquinone that is derived from mitomycin C. It has a rather high molecular weight of 288 kD and hence does not easily penetrate the bladder epithelium. It is rapidly cleared in the systemic circulation and requires activation by a reductase that is found at relatively higher levels in bladder tumor tissue compared with normal bladder epithelium. A phase II study involving Ta/T1 marker lesions suggested an excellent pathological response rate of 67% (van der Heijden et al., 2006). Side effects mainly consisted of cystitis and hematuria with only 9% of patients experiencing grade 3 toxicity. Subsequent phase III trials using this agent for immediate perioperative instillation have not yielded expected results and further trials are currently ongoing.

Combination Therapy

Combining mechanisms of different agents is a logical and often successful approach to improve response rates for systemic therapy. However, studies have not identified clear benefit to doing so in intravesical therapy with a general theme of increased local side effects with modest outcome improvement (Isaka et al., 1992; Sekine et al., 1994).

There has been more interest in combination intravesical chemotherapy using mitomycin and gemcitabine in sequence as well as mitomycin and docetaxel. Breyer et al. (2010) demonstrated a good response rate to sequential mitomycin and gemcitabine in patients who were BCG refractory. This was confirmed in a larger multi-institutional study in which a durable recurrence-free rate of 38% was found in a cohort of 47 patients (Lightfoot et al., 2014). In this approach gemcitabine is instilled first at a dose of 1000 mg and left in place for 60 to 90 minutes. After draining the gemcitabine, this is followed by mitomycin C in the dose of 40 mg for another 60 to 90 minutes. It is important to instill the mitomycin second because it is a vesicant, and irritation caused by the mitomycin can make it hard for the patient to retain the gemcitabine as well as resulting in significantly greater local side effects. A combination of gemcitabine and docetaxel has also been used for sequential intravesical instillation (Steinberg et al., 2015). A 34% recurrence-free rate at 2 years has been achieved in a pilot study of 45 patients, indicating that this may be a promising approach. The main advantage of this regimen compared with other combination intravesical therapies may be the low incidence of side effects while maintaining a similar response. A combination of chemotherapy and BCG was evaluated in prospective trials by several investigators. The EORTC reported a 46% complete response rate when a solitary marker tumor was intentionally not resected and patients were subsequently given sequential MMC and BCG (van der Meijden et al., 1996). In a study of 188 patients with Ta and T1 lesions, no difference was seen with regard to recurrence, progression, or side effects in those patients treated with BCG and MMC compared with those treated with MMC alone. There was actually a significantly longer disease-free interval in the BCG monotherapy arm (55%) compared with the same combination arm (45%) in another study of 314 patients (Malmstrom et al., 1999; Solsona et al., 2002). **Thus no clear advantage is obtained with sequential therapy, or chemotherapy and BCG regimens in the absence of electromotive current using any of the combinations explored to date** (Nieder et al., 2005; Rintala et al., 1995, 1996; Witjes et al., 1998). **Salvage approaches using sequential combination chemotherapy using gemcitabine and mitomycin or docetaxel may yield reasonable response and recurrence-free survival in a subset of patients, although these data must be confirmed by larger studies.**

Key Points: Intravesical Chemotherapy

- Intravesical chemotherapy has a clear impact on tumor recurrence when immediately instilled after TURBT and in the adjuvant setting. There is no clear evidence of an impact on progression.
- Combinations of various chemotherapeutic agents and chemotherapy combined with BCG have not demonstrated major benefit combined with

single-agent treatment, with the exception of IFN.

- In general, side effects of chemotherapy tend to be less common and less severe than those for BCG, but BCG is more efficacious.
- Combination intravesical chemotherapy may have a role in treating BCG refractory cancers

Refractory High-Grade Disease

Recurrent or persistent disease after an initial 6-week course of BCG has been traditionally referred to as *BCG failure*, although this term has been poorly defined in the past. **Persistent disease after BCG therapy can be categorized as BCG refractory disease.** Current consensus is that BCG-refractory disease is defined in patients who have persistent disease despite receipt of 2 induction courses of BCG, induction plus maintenance (usually within 6 months), or intolerance of BCG (Jarrow et al., 2014). **BCG-refractory patients in particular are an especially high-risk group and should be strongly considered for immediate cystectomy if young and in generally good health** (Chang et al., 2016; Herr and Dalbagni, 2003). Additional intravesical therapy for BCG refractory disease should be reserved for patients who refuse or are too ill to undergo cystectomy or on defined investigational protocols.

The necessity of biopsy to determine BCG response is unclear, although it should be strongly considered in high-risk patients to determine disease status at this key point in time. Urine cytology can be useful in this setting. Dalbagni et al. (1999) reported minimal usefulness of routine biopsy after BCG if cystoscopy and urinary cytology were both negative. Whereas 5 of 11 patients with erythematous bladder mucosa and positive cytology had positive bladder biopsies, none of 37 with erythematous lesions and negative cytology were positive, and only 1 in 13 patients with a normal mucosa had a positive biopsy (Dalbagni et al., 1999). Other studies have suggested that the value of routine post-BCG biopsy is limited (Dalbagni et al., 1999). UroVysion FISH (Abbott Molecular, Chicago, IL) conversion from positive to negative has been shown to correlate with BCG response in single-center studies (Kipp et al., 2005; Whitson et al., 2009).

Declaring failure may take up to 6 months because the response rate for patients with high-grade bladder cancer treated with BCG rose from 57% to 80% 3 to 6 months after therapy (Herr and Dalbagni, 2003). This is particularly true for patients with CIS because it appears that there is a delayed resolution of CIS that can occur between 3 and 6 months. Clearly, the tumoricidal activity continues for some period after cessation of therapy. This has obvious implications not only for declaring BCG failure and the need for subsequent therapy, but also for interpretation of success rates of salvage protocols if administered soon after therapy.

Management of Refractory High-Grade Disease

Although most urologists will administer an initial 6-week course of intravesical therapy for high-risk patients, **management of patients with persistent disease after the first course is more complex. Such patients are at increased risk of progression, which is particularly likely in the event of early recurrence, progression while on therapy, or multiple recurrences.**

If the initial treatment was chemotherapy, a course of BCG should be considered. BCG has demonstrated superiority to repeat courses of chemotherapy in this setting because the latter will lead to only an approximately 20% disease-free survival (Malmstrom et al., 1999; Steinberg et al., 2000). **For patients who have failed BCG, a second course still gives a 30% to 50% response** (Brake et al., 2000; Pansadoro and De Paula, 1987). **A second course of BCG is recommended for patients with intermediate- or high-risk disease if persistent or recurrent Ta disease or CIS is noted after a single course of intravesical BCG in most recent AUA/SUO guidelines** (Chang et al., 2016). Patients who cannot tolerate BCG for any reason may be considered for salvage chemotherapy, but the risk of failure and progression is high.

Further courses of BCG or chemotherapy beyond two are not recommended because they will fail 80% of the time, although recent studies suggest some potential for newer agents (Skinner et al., 2013). **Rapid disease progression is common in such patients,** so salvage chemotherapy, investigational protocols, and IFN alone or in combination with reduced doses of BCG may be appropriate only for patients who are unwilling or unable to undergo surgery even after being informed of their risks (Catalona et al., 1987). Current guidelines recommend consideration of clinical trials as the first option followed by radical cystectomy. Repeated attempts at intravesical therapy beyond 2 years from initial tumor diagnosis should be discouraged because there is a significant drop in cancer-specific survival in patients with high-risk tumors (particularly T1) who wait longer than this duration despite ultimate performance of radical cystectomy (Herr and Sogani, 2001).

Role of Alternative Options for Refractory Disease

Photodynamic therapy (PDT) relies on a specific light interaction with a

photosensitized target tissue. This treatment is performed by administering a photosensitizing agent such as porfimer sodium (Photofrin) systemically or hexaminolevulinate (HAL) intravesically. The patient is then given an intravesical treatment with light irradiation. After excitation by light, the photosensitizer reacts with molecular oxygen to form free radicals and reactive singlet oxygen to have cytotoxic effect.

The response rate in CIS patients from combined series is 66%, with a duration of 37 to 84 months (Jocham et al., 1989; Nseyo et al., 1997, 1998; Walther, 2000). For patients with papillary disease, an overall response rate of 51% has been achieved with a median time to recurrence of 24 to 48 months (Naito et al., 1991; Nseyo et al., 1997, 1998; Walther, 2000). PDT has been limited by significant side effects such as bladder contracture or irritability (50%) and dermal sensitivity (19%) (Naito et al., 1991; Nseyo et al., 1997, 1998; Uchibayashi et al., 1995). More recent trials have demonstrated improved tolerability with HAL and an incoherent white light source for irradiation. One such trial involved 2 treatments with HAL-PDT 6 weeks apart with 2 of 17 patients tumor free at 21 months (Bader et al., 2013).

Research efforts have been directed at development of improved photosensitizers and modifications in laser dosimetry (Kriegmair et al., 1996a; Nseyo et al., 1997, 1998). HAL, a more lipophilic ester of 5-ALA, generates a sensitizer called *protoporphyrin IX* that appears more tumor specific, although clinical data are limited (Datta et al., 1998). Radachlorin is composed of three chlorins and appears promising, at least in the setting of BCG-refractory high-grade disease (Lee et al., 2013).

Radiation therapy in the treatment of NMIBC is typically restricted to individuals who refuse cystectomy after the failure of intravesical therapy or who are unsuitable for major surgery (Kim et al., 2000). A complete response to radiation therapy and TUR is attainable in 50% to 75% of patients, but the additional benefit of radiation to TUR remains unclear (De Neve et al., 1992; Jansson et al., 1998; Rozan et al., 1992). Five-year response rates are 44% to 60%. There is no significant effect on CIS. Because of reports that up to 50% of patients will develop progression and a high likelihood of death (Rödel et al., 2001), there is a limited role for radiation therapy other than for palliative purposes in this population. Combinations of radiation and chemotherapy have shown promise but have not reached widespread use (Gray et al., 2013).

Checkpoint inhibitors are a newer class of therapy under investigation for use in NIMBC. These agents represent systemic immunotherapy with a mechanism of action that involves disrupting the interaction between programmed death ligand-1 (PD-L1), and programmed cell death protein-1 (PD-1). In normal immune function, the interaction between these receptors and their ligands regulates T-cell activation and acts as an inhibitory signal in the generation of immune response against a tissue. A number of malignancies, including urothelial cell carcinoma, have been found to upregulate this interaction to prevent immune response against tumor cells. Over the past several years, monoclonal antibodies inhibiting this interaction, and thereby activating cytotoxic T-cell function against tumor cells, have been developed, with urothelial cell carcinoma exhibiting susceptibility to such therapy (Mukherjee et al., 2018).

Several agents such as atezolizumab (PD-L1 inhibitor) have been approved for patients with locally advanced or metastatic bladder cancer who progressed after chemotherapy (Rosenberg et al., 2016). Several additional agents including avelumab and durvalumab have also been approved for this indication. Nivolumab and pembrolizumab are PD-1 receptor monoclonal antibodies that are approved for similar indications in advanced disease, post-chemotherapy, and for patients not eligible for cisplatin.

Given the response of urothelial carcinoma in advanced disease as well as the long-standing role for BCG immunotherapy in NMIBC, several current trials are aiming to assess the value of checkpoint inhibitors in NMIBC. Current phase II clinical trials are ongoing in patients with BCG-refractory disease evaluating the potential benefit of atezolizumab, durvalumab, and pembrolizumab. Furthermore, additional trials are underway using checkpoint inhibitors in combination with concurrent intravesical BCG (Mukherjee et al., 2018). Although the efficacy of these agents in NMIBC remains under investigation, checkpoint inhibitors represent a promising new line of immunotherapy for this disease.

Key Points: Management of Refractory Disease

- Patients who experience failure of an initial course of intravesical therapy after TURBT are at high risk of recurrence or progression.
- Failure of initial chemotherapy or BCG is most appropriately treated with a subsequent course of BCG because its efficacy in this setting is significantly greater than that of chemotherapy.

- After failure of a second course of intravesical therapy, patients can be enrolled in clinical trials of new agents, consider combination intravesical therapy, or proceed to cystectomy.

Role of “Early” Cystectomy

Despite local therapy, many cases of high-grade NMIBC will progress to invasion and risk of cancer death. Although the initial response rate to BCG therapy in CIS patients can be above 80%, patients in whom treatment fails will have a 50% chance of disease progression and potential for disease-specific mortality (Catalona et al., 1987; Nadler et al., 1994). Early (3-month) failure for T1 tumors after BCG is associated with an 82% progression rate, compared with a 25% progression rate in patients who do not experience treatment failure at 3 months (Herr et al., 1997; Herr, 2000a). Up to 20% of patients with CIS die of UC within 10 years (Herr et al., 1989); each occurrence of T1 tumors is associated with a 5% to 10% chance of metastasis (Herr and Sogani, 2001), and residual tumor found on repeat resection in these patients is associated with an 82% chance of development of muscle invasion (Herr et al., 1997). These data offer compelling evidence of the potential to underestimate disease status in high-risk patients.

Cookson et al. (1997) reported that 27% of high-risk patients treated initially with aggressive intravesical therapy did well and died of other causes, and the same low number survived with an intact, functioning bladder 15 years after diagnosis. However, approximately half of patients experienced progression, and one-third died of their disease. In contrast, **patients who undergo immediate cystectomy for clinical T1 tumors benefit from more accurate pathological staging in addition to a 10-year disease-free survival of 92%, compared with 64% of those with clinical T1 tumors who were found to actually have muscle invasion at the time of cystectomy** (Bianco et al., 2004).

Despite the benign connotation of the term *superficial* formerly applied, up to 50% of patients with presumed non–muscle-invasive high-grade disease who undergo cystectomy will actually be found to have muscle-invasive disease. Such procedures have traditionally been termed *early cystectomy* on the basis of the fact that they are performed before the traditional surgical indication of documented muscle invasion. Up to 15% will already have micrometastases (Chang and Cookson, 2005) and a delay in cystectomy of even 12 weeks is associated with poorer survival; therefore some of these procedures do not seem to be early enough (Chamie et al., 2013; Sanchez-Ortiz et al., 2003).

The risk of progression must be weighed against the risk, morbidity, and impact on quality of life for cystectomy. Thus **a reasonable goal may be, as termed by Chang and Cookson** (2005), **"timely" cystectomy for patients at risk.**

Ten-year survival after cystectomy for non–muscle-invasive cancer can range from 67% to 92% (Amling et al., 1994; Freeman et al., 1995). **However, despite the bias that substantial progression can be averted with the benefit of early detection and close surveillance in patients whose tumors are identified before muscle invasion, it appears that such patients who progress to having muscle invasion may have a poorer prognosis than do those who have muscle-invasive disease on initial presentation** (Lee et al., 2007; Schrier et al., 2004). **Thus overconfidence in disease control status with high-risk patients on surveillance creates a false sense of security.**

The AUA guidelines suggest cystectomy as the first option for patients with refractory high-grade disease after an initial course of intravesical therapy (see later). Nevertheless, **fewer than one in five American urologists surveyed stated that they would recommend cystectomy for their patients with CIS refractory to two courses of intravesical BCG, a group with an 80% risk of failure or progression** (Joudi et al., 2006a). **Cystectomy in that setting, or for persistent high-grade papillary disease after two courses of intravesical therapy, is the standard of care and should not be considered "early."**

The role of surgical approaches involving potential oncologic concessions such as seminal and nerve-sparing cystectomy in such patients theoretically at lower risk of recurrence compared with patients with muscle invasion remains unknown (Hautmann and Stein, 2005). The availability of neobladder for less disfiguring urinary diversion has been reported to decrease the delay in treatment of such patients, potentially leading to significantly improved disease-free survival (Hautmann and Paiss, 1998). The impact on disease outcomes is unproven.

Cystectomy should also be considered in patients whose cancer cannot be reasonably controlled through resection: bulky tumors, inaccessible because of a large bladder or urethral stricture disease, or otherwise not amenable to safe removal endoscopically.

In summary, **radical cystectomy offers the most accurate pathological staging option and should be strongly considered for patients with NMIBCs that are high grade and invading deeply into lamina propria, exhibit**

lymphovascular invasion, are associated with diffuse CIS, are in diverticula, substantially involve the distal ureters or prostatic urethra, are refractory to initial therapy, or are too large or anatomically inaccessible to be removed in their entirety endoscopically. It can also be used in patients who understand the risks and benefits of bladder preservation versus cystectomy and request definitive therapy (Stein, 2003). **Current AUA guidelines suggest radical cystectomy in patients who are fit for surgery and have persistent high-grade T1 disease on repeat resection, or T1 tumors with associated CIS, LVI, or variant histologies. These same guidelines also suggest cystectomy in high-risk patients with persistent or recurrent disease within 1 year after treatment with two induction cycles of BCG or BCG maintenance** (Chang et al., 2016). Partial cystectomy has limited data but may be a bladder preservation option in appropriately selected patients, between the extremes of TURBT combined with intravesical therapy and radical cystectomy.

Key Points: Early Cystectomy

- Patients at high risk for progression should be considered for cystectomy.
- Failure to respond to an initial course of intravesical therapy is occasion to reconsider cystectomy.
- Failure to respond to a second course is an indication for immediate cystectomy unless contraindicated or the patient chooses to pursue clinical trials or newer proven intravesical options if evidence builds for their use.

Surveillance and Prevention

Although bladder cancer is less common than prostate cancer, expenditures are almost twice as high for bladder cancer because of its chronic nature and the need for long-term surveillance. According to the Agency for Healthcare Research and Quality, annual expenditures were $2.2 billion in 2003 for bladder cancer versus $1.4 billion for prostate cancer (Donat, 2003). A significant portion of this cost is associated with surveillance (Hedelin et al., 2002).

Surveillance strategies for UC recurrence have historically relied on the diagnostic combination of cystoscopy and urinary cytology. In clinical practice, only 40% of patients actually comply with a standard surveillance protocol (Schrag et al., 2003). Although the accuracy of both tests relies on subjective and operator-dependent interpretation of visible findings, their traditional presumed status as the gold standard has been widely accepted (Brown, 2000). The timing and frequency of surveillance cystoscopy, cytology, and upper tract imaging can be varied based on risk of recurrence and progression. To aid urologists in determining this risk for patients, several models and risk stratification algorithms exist, including AUA/SUO guideline stratification outlined in Table 136.2, and EORTC risk tables, which take into account number of tumors, tumor size, prior recurrence rate, T stage, CIS, and grade (Sylvester et al., 2006). Using these risk stratification systems surveillance can be tailored to individual patients, and a summary of suggested surveillance protocols consistent with most recent AUA/SUO guidelines is provided in Table 136.5.

TABLE 136.5

2016 AUA/SUO Guideline Suggested Surveillance Strategies

RISK	TUMOR STATUS	CYSTOSCOPY SCHEDULE	UPPER TRACT IMAGING
Low	Solitary Ta low grade	3 mo after initial resection Annually beginning 9 mo after initial surveillance if no recurrence Consider cessation at 5 or more years Consider cytology or tumor markers	Not necessary unless hematuria present

Intermediate	Multiple Ta low grade Large tumor Recurrence at 3 mo	Every 3–6 mo for 1-2 yr Every 6–12 mo for subsequent 2 yr Annual cystoscopy thereafter Consider cytology or tumor markers Restart clock with each recurrence	Consider imaging at 1- to 2-yr intervals, especially for recurrence Imaging for hematuria
High	Any high grade (including CIS)	Every 3–4 mo for 2 yr Semiannually for 2 yr Annually for lifetime Cytology at same schedule Consider tumor markers Restart clock with each recurrence	Imaging annually for 2 yr, then consider lengthening interval

CIS, Carcinoma in situ.

Modified from Chang et al.: *Diagnosis and treatment of non-muscle invasive bladder cancer*, AUA/SUO Guideline, 2016.

Cystoscopic Surveillance

Office-based cystoscopy offers rapid, relatively painless visual access to the urothelium. Papillary tumors arising from the smooth bladder surface are readily identified. CIS is classically described as a velvety red mucosal patch, although the reliability of such findings is less clear. Nevertheless, for office-based diagnosis it allows identification of the site and characteristics of most tumors. **There is a high positive predictive value with cystoscopy because most lesions believed to be malignant are proven so pathologically. The endoscopic appearance cannot reliably predict tumor stage or grade, although sessile morphology and/or the presence of necrosis suggests high-grade disease likely to be invasive.**

Cystoscopy is usually performed in the outpatient setting, often using digital flexible cystoscopes in most settings. Complete visualization of the bladder mucosa is possible in a matter of seconds in most patients. Using the same technology for flexible cystoscopy as described earlier for HAL fluorescence rigid cystoscopy, phase II studies have had mixed results but suggest that office-based fluorescence cystoscopy can improve the detection of CIS and papillary tumors (Loidl et al., 2005; Witjes et al., 2005).

The majority of men and women tolerate office-based cystoscopy with minimal discomfort. **Intraurethral injection of local anesthetics is almost universal among urologists. Data from randomized trials are contradictory** (Palit et al., 2003; Rodriguez-Rubio et al., 2004) **and one meta-analysis indicated no benefit (**Patel et al., 2008b**), whereas another indicated there was a benefit in pain reduction when anesthetic containing lubricating gel was used** (Aaronson et al., 2009). Two recent studies actually found that pain experience was higher with the use of local anesthetics than in patients cystoscoped using aqueous lubricant alone (Chen et al., 2005; Ho et al., 2003). Use of a video monitor allows patients to see and understand the findings, theoretically distracting them from any discomfort. Men who are able to do so tolerate the procedure with approximately 50% less pain than those who cannot see their findings on the monitor (Patel et al., 2007). Instillation of anesthetic gel into the urethra has not been found to be of significant benefit in women, probably because of the straighter urethra (Patel et al., 2008a).

The bladder should be emptied before cystoscopy. Aspiration with use of a 60-mL syringe attached to the irrigant port is occasionally necessary during the procedure. This can further lessen clouding. A systematic approach is mandatory to ensure that all urothelium is visualized.

The use of air cystoscopy, as opposed to fluid instillation, has also been evaluated and found to potentially aid in visualization during active hematuria (Ciudin et al., 2013) and may provide a viable alternative in settings where sterile fluid irrigant is unavailable (Dutta et al., 2017).

Attempts have been made to modify the previously described surveillance schedule with use of decision analysis tools (Abel, 1993; Kent et al., 1989). Several authors recommend termination of surveillance at 5 or more years for low-risk patients (Haukaas et al., 1999). However, the actual cost of surveillance cystoscopy was responsible for only 13% of the expenditures for bladder cancer care in one study, so the financial opportunity may be limited for such efforts (Hedelin et al., 2002; Schoenberg et al., 2000). In addition, the risk of recurrence and potential for progression exists beyond this period. Reports of late recurrences of high-grade cancer years after the original tumor temper some authors’ enthusiasm for terminating surveillance at any point (Leblanc et al., 1999; Morris et al., 1995; Thompson et al., 1993; Zieger et al., 2000). The AUA guidelines recommend cystoscopic surveillance based on risk stratification of the tumor into low-, intermediate- and high-risk categories. The recommended surveillance schedule is shown in Table 136.5. Current AUA guidelines indicate that surveillance beyond 10 years can be decided on a case-by-case basis after a discussion between the patient and the urologist (Chang et al., 2016).

Other investigators have examined the predictive impact of early or multiple recurrences and how this may affect surveillance (Holmäng et al., 1995; Parmar et al., 1989; Reading et al., 1995). **Tumor recurrence on initial 3-month cystoscopy and number of tumors on initial resection (single or multiple) provide the most predictive information with regard to recurrence in several studies. Absence of recurrence on the 3-month surveillance cystoscopy in patients with Ta low-grade tumors is associated with recurrence rates so low that annual cystoscopy appears safe even at that point (beginning 12 months after the initial resection)** (Fitzpatrick et al., 1986; Frydenberg et al., 2005; Olsen and Genster, 1995). Finally, patients with a negative cystoscopy and a negative UroVysion assay (see later) are at low risk of recurrence in the following 6 to 12 months, creating opportunity to individualize the surveillance schedule (Sarosdy et al., 2002).

Urine Cytology

Cytology involves microscopic evaluation of stained cellular smears from the urine. Unlike tumor markers, urinary cytology represents a pathologist's interpretation of the morphologic features of shed urothelial cells rather than an objective laboratory test. Poor cellular cohesion in high-grade tumors, especially CIS, enhances the yield.

Its high specificity is the most important feature of cytology because a **positive reading regardless of cystoscopic or radiographic findings suggests the existence of malignancy in the vast majority of patients.** Even in the setting of UC, of patients with a negative workup (cystoscopy and upper tract imaging) with a persistently positive cytology, 40% were found to have genitourinary cancer within 24 months (Nabi et al., 2004).

Although cytology has traditionally been believed to have high sensitivity for high-grade cancer, recent studies suggest that only 58% of bladder tumors are identified using cytology. Its low sensitivity is not limited to low-grade tumors because only 71% of high-grade cancers were identified. **Cumulative data from series published after 1990 reported that cytology actually identified (using the older grading system) 11% of grade 1, 31% of grade 2, and only 60% of grade 3 tumors** (Halling et al., 2000). In contrast, they observed that these recent findings were well below those reported before 1990, when the sensitivity of cytology was 94% for grade 3 tumors, but could find no explanation for this deterioration. These findings are supported by numerous other studies and emphasized by a recent multicenter study involving several institutions noted for bladder cancer expertise that found cytology had an overall sensitivity of 15.8% (Grossman et al., 2005).

Thus cytology has high specificity but low sensitivity for high-grade and low-grade tumors, including CIS.

Tumor Markers

Many attempts have been made to develop a UC biomarker test to complement or replace urinary cytology. Most of these have had adequate sensitivity but poor specificity, resulting in substantial false-positive readings, creating the need for further diagnostic testing. Current urinary markers have been developed to detect tumor-associated antigens, blood group antigens, growth factors, cell cycle and apoptosis, and extracellular matrix proteins. The most significant issue limiting widespread adoption of tumor markers is the lack of prospective data to support their impact on prognosis or disease management (Lokeshwar et al., 2005).

The qualitative point-of-care test **BTA stat** (Polymedco, Cortlandt Manor, NY) and the quantitative **BTA TRAK** (Polymedco) assay detect human complement factor H–related protein. The overall sensitivity of these tests ranges from 50% to 80%, whereas the specificity is between 50% and 75%. These tests are more sensitive than cytology particularly for low-grade tumors, but their results can be falsely positive in patients with inflammation, infection, or hematuria (Liou, 2006).

ImmunoCyt (DiagnoCure, Saint Foy, Canada) is a hybrid of cytology and an immunofluorescence assay. Three fluorescent-labeled monoclonal antibodies are targeted at a UC variant of carcinoembryonic antigen and two bladder mucins. Sensitivity and specificity are reported to be 86% and 79%, respectively. The assay has not been shown to be affected by benign conditions, but interpretation is complex and operator dependent (Têtu et al., 2005; Toma et al., 2004). This test may be helpful in adjudicating atypical cytology because it has a high negative predictive value in this setting (Odisho et al., 2013).

The **NMP22 BladderChek** Test (now marketed as the Alere NMP22 BladderChek, Alere, St. Louis, MO) is based on the detection of nuclear matrix protein 22, part of the mitotic apparatus released from urothelial nuclei on cellular apoptosis. The protein is elevated in UC, but it is also released from dead and dying urothelial cells. Benign conditions of the urinary tract such as stones, infection, inflammation, hematuria, and cystoscopy can cause a false-positive reading. A laboratory-based, quantitative immunoassay and a qualitative point-of-care test are available. The sensitivities and specificities range from 68.5% to 88.5% for sensitivity and from 65.2% to 91.3% for specificity (Liou, 2006). A multi-institutional trial involving 1331 patients showed that, overall, the NMP22 was more sensitive than cytology but less specific. Sensitivities were 50% and 90% for noninvasive and invasive cancer, respectively, with an overall sensitivity of 55.7%. Overall specificity was higher for cytology at 99.2% compared with NMP22 at 85.7%. The sensitivity of cystoscopy in this study was 88.6%, but when combined with NMP22, this increased to 93.7% (Grossman et al., 2005).

UroVysion (Abbott Molecular, Des Plaines, IL) is a cytology-based test that uses FISH of DNA probes or labels specifically chosen to identify certain chromosomal foci. Probes to identify aneuploidy of chromosomes 3, 7, and 17 are combined with a probe to the 9p21 locus. Probes can be developed to identify essentially any locus, but this combination has the best sensitivity and specificity (Halling et al., 2000). Cumulative data from comparative studies show sensitivity for cytology compared with FISH of 19% versus 58% for grade 1, 50% versus 77% for grade 2, and 71% versus 96% for grade 3. Similar findings occurred by stage, wherein cytology compared with FISH sensitivity was 35% versus 64% for Ta, 66% versus 83% for T1, and 76% versus 94% for muscle-invasive carcinoma (Jones et al., 2006; Fig. 136.10).

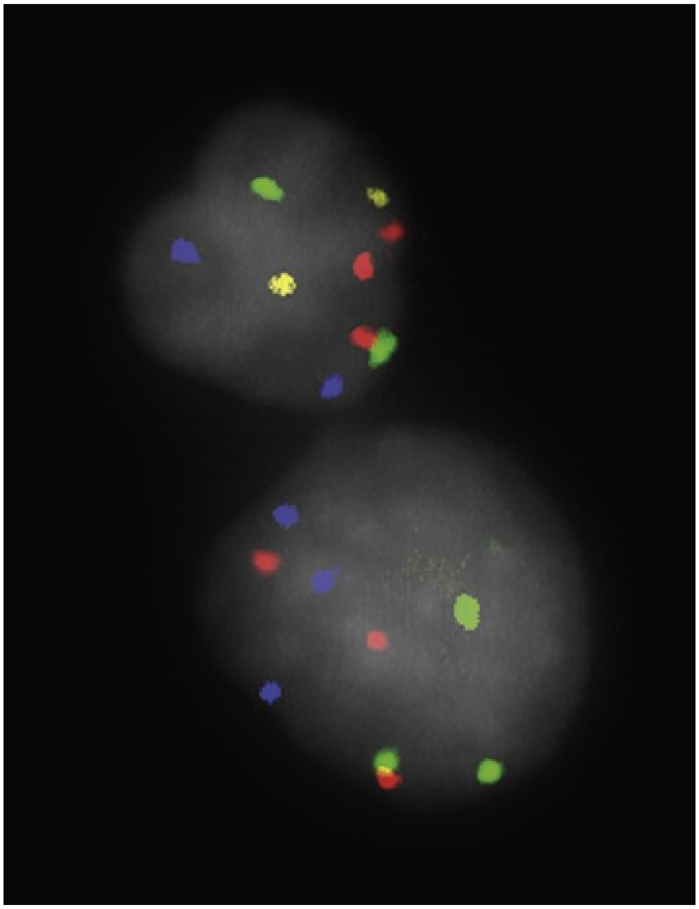

FIG. 136.10 An abnormal enlarged cell *(lower right)* demonstrates three copies of chromosome 3 *(red),* chromosome 7 *(green),* and chromosome 17 *(aqua)* on use of fluorescence in situ hybridization. Homozygous deletion of band 9p21 locus *(yellow)* is also present. (Courtesy Raymond Tubbs, MD, Department of Laboratory Pathology, Cleveland Clinic Foundation.)

Notably, cytology detected only 67% of patients with CIS versus 100% detection by FISH in comparative studies. **UroVysion has the highest specificity of the available tumor markers.** It will, however, detect chromosomal changes before the development of phenotypic expression of malignancy, so it leads to an “anticipatory positive” reading in some patients. Such readings are often not false positives and will lead to identification of clinical tumors within 3 to 15 months in the majority of cases (Sarosdy et al., 2002). Moreover, patients testing negative are unlikely to experience tumor recurrence in less than 1 year (Yoder et al., 2007). Previous studies have suggested that a persistently positive UroVysion FISH after BCG may predict a poor response to BCG with higher likelihood of recurrence and progression (Kamat et al., 2012). Thus the use of UroVysion FISH may allow identification of patients at risk of recurrence versus those unlikely to develop recurrence, and subsequent individualizing of surveillance and treatment protocols.

UroVysion has also been shown to clarify equivocal findings in patients with atypical or negative cytology (Skacel et al., 2003). It is not affected by hematuria, inflammation, or other factors that can cause false-positive readings with some tumor markers, so it appears to be useful as a marker of BCG response (Kipp et al., 2005; Whitson et al., 2009). “Non-diagnostic” UroVysion reports identifying limited cellularity or positive cells at numbers below defined standards can be regarded as negative and are not associated with increased risk of bladder cancer recurrence in the future compared with expectations with “normal” readings (Nguyen et al., 2009).

CxBladder Monitor is a noninvasive urine monitoring test using gene expression and clinical patient data to generate a test to assess for evidence of urothelial carcinoma. This test has been shown to outperform other studies such as cytology and NMP22 with a sensitivity of 91% and negative predictive value of 96% (Lotan et al., 2017).

A retrospective study suggests that a multiplex of eight biomarkers in combination may improve performance compared with currently available markers if validated in further studies (Rosser et al., 2013).

The usefulness of tumor markers and the choice of which one to use is not clear at this time. For example, if indication for biopsy in the operating room is the end point, then high specificity is desired to limit the number of negative biopsies. On the other hand, if increasing the interval of cystoscopic surveillance is the end point, then high sensitivity, particularly for high-grade tumors, is desired. Defining that a patient has a low likelihood of recurrence within the following year can allow individualization of surveillance protocols (see Table 136.5; Grossman et al., 2006).

Current AUA guidelines discourage the use of urinary markers to replace cytology for surveillance of NMIBC. They do, however, suggest consideration of urinary markers to assess response to intravesical therapy as well as for the adjudication of atypical or equivocal cytology results (Chang et al., 2016).

Extravesical Surveillance

The proportion of patients developing **upper tract UC** after treatment of non–muscle-invasive disease has been reported as 0.002% to 2.4% over intervals of 5 to 13 years (Holmäng et al., 1995; Oldbring et al., 1989; Sadek et al., 1999; Shinka et al., 1988), although the risk increases substantially over time to as high as 18% in very high-risk populations (Herr et al., 1997). Synchronous tumors were detected in no patients (0) with grade 1 (using the prior grading system) tumors, 1.1% with grade 2, and 1.3% with grade 3, as well as 0 for low-grade Ta and 7% for T1 (Herranz-Amo et al., 1999). **The Surveillance, Epidemiology, and End Results (SEER) database showed that only 0.8% of bladder cancer patients develop subsequent upper tract tumors, so surveillance is of limited value unless the patient has hematuria or a high-grade tumor, especially if it is near the ureteral orifice** (Wright et al., 2009). In a review of 591 patients with median follow-up of 86 months, upper tract recurrence was 0.9% in low-risk patients (solitary, low-grade, low-stage Ta/T1), 2.2% in patients at intermediate risk (recurrent or multifocal disease), and 9.8% in high-risk patients including intravesical chemotherapy failures (Hurle et al., 1998). **AUA guidelines suggest that clinicians should not perform routine surveillance upper tract imaging in asymptomatic patients with a history of low-risk NMIBC. In the setting of intermediate- or high-risk patients, guidelines suggest consideration of surveillance upper tract imaging at 1- to 2-year intervals, but there are few data evaluating the benefit of such imaging** (Chang et al., 2016).

Multiphasic CT urography has become the preferred technology for the evaluation of hematuria, but its role in the evaluation of patients with NMIBC has not been extensively reported (Davis et al., 2012; Herts, 2003). Magnetic resonance urography and renal ultrasound are potential alternatives in select patients. Retrograde ureteropyelography represents an additional alternative option to image the upper tracts in patients with NMIBC, particularly in those unable to undergo CT urography secondary to contrast allergies or renal insufficiency. Although this does require procedural instrumentation, it can often be done in the same setting with TURBT.

Although infrequent, the appearance of upper tract disease is associated with mortality rates of 40% to 70%. Patients with high-risk disease treated with BCG experience upper tract recurrence risk of 13% to 18% (Herr et al., 1997; Miller et al., 1993). The risk for recurrence in this population appears greatest over the first 5 years after treatment (median time to detection, 56 months) yet persists at least 15 years.

Selective cytology of the upper tract may increase the yield of upper tract lesions detected, but, in the presence of a bladder tumor, selective upper tract cytology may be falsely positive and is not recommended for most patients (Sadek et al., 1999; Zincke et al., 1983).

Secondary tumor involvement of the prostatic urethra and ducts by UC may be detected in 10% to 15% of patients with high-risk non–muscle-invasive disease within 5 years and in 20% to 40% within 10 years (Donat, 2003). Patients who have refractory disease are at risk for extravesical recurrence in the prostatic fossa in approximately one-third of cases, 44% of which are fatal (Herr et al., 1988). Involvement of the prostatic ducts by low-grade UC is usually be managed by complete TURP for disease eradication and to facilitate contact of intravesical therapy to the prostatic urethra. Involvement of the ducts by high-grade disease is best managed by radical cystoprostatectomy, and consideration of urethrectomy should be made, especially if tumor is present near or at the surgical margin (Liedberg et al., 2007).

In summary, surveillance strategies should be individualized on the basis of the risk of recurrence in the bladder and extravesical sites (see Table 136.5).

Secondary Prevention Strategies

Lifestyle changes and chemoprevention could potentially reduce the risk of recurrence and have been considered in the management of patients with non–muscle-invasive disease.

Lifestyle changes are particularly important because UC is directly linked to environmental factors in the majority of cases. **Smoking cessation, increased fluid intake, and a low-fat diet may reduce the risk of recurrence**; the former is paramount. **Increased hydration reduces the concentration and dwell time of carcinogens** and thereby reduces the risk of malignant transformation within the urothelium (Jiang et al., 2008). The Physician Health Study showed an inverse correlation between fluid intake and the incidence of UC on longitudinal follow-up, but this simple measure may also be of benefit for secondary prevention for patients who already have a history of UC (Michaud et al., 1999). **High fat and cholesterol intake are now firmly established as risk factors** for many cancers, although the mechanisms are not as well defined as for other malignancies (Steineck et al., 1990).

A variety of agents have been investigated for chemoprevention strategies for patients with UC, including retinoids (i.e., vitamin A and its analogues) (Becci et al., 1978; Eichholzer et al., 1996; Sporn et al., 1977; Steinmaus et al., 2000);

pyridoxine (vitamin B_6) (Byar and Blackard, 1977; Newling et al., 1995); α-tocopherol (Lotan et al., 2005; Virtamo et al., 2000); and difluoromethylornithine (DFMO) (Messing et al., 2005). However, none of these agents has proven useful in rigorous trials. Isoflavones were studied for the same purpose, but the studies were abandoned because of higher bladder cancer risk in the patients consuming greater amounts of soy products (Sun et al., 2004). High-dose multivitamins were shown to decrease the incidence of recurrence especially if administered along with intravesical BCG therapy (Lamm et al., 1994). However, a randomized trial conducted subsequently failed to confirm this initial finding (Nepple et al., 2010).

Key Points: Surveillance and Prevention

- Cystoscopy is the hallmark of surveillance. The surveillance schedule should be individualized on the basis of risk stratification of the most recently resected tumor.
- Table 136.5 demonstrates reasonable surveillance protocols based on clinical scenarios.
- A number of tumor markers have shown the ability to improve the sensitivity of cytology, but specificity is lower for most.
- Increased fluids, smoking cessation, and a low-fat diet are recommended.
